### 34.6.3.10 Non-periodic Transmit FIFO/Queue Status Register (USBHS\_HNPTXSTS)

This read-only register contains free space information for the non-periodic TxFIFO and non-periodic transmit request queue.

This register is enable only in host mode, not in device mode.

### 34.6.4 USBHS Host Mode Register

The host mode register affects the operation of the module in host mode. The host mode registers must not be accessed in device mode, as the results produced are ambiguous.

#### 34.6.4.1 Host Configuration Register (USBHS\_HCFG)

This register configures the module after power-on. Do not modify this register after initializing the host.

| 15:0  | FRIVL    | Frame interval | <p>The value programmed by the application in this field is used to specify the time interval between two consecutive SOF(FS) or Keep-Alive tokens(LS). This field contains the number of PHY clocks that make up the desired frame interval. The application can only write values to this register after setting the port enable bit (PENA bit in USBHS_HPRT) of the host port control and status register to 1. If no value is programmed, the module calculates based on the PHY clock specified in the FS/LS PHY clock selection field (FSLSPCS in USBHS_HCFG) of the host configuration register. Do not change the value of this field after initial configuration. Setting value=frame interval (ms) ×(PHY clock frequency) -1</p> <div>  <b>Notice</b><br/>           When the application needs to change the frame interval time, it can modify the FRIVL bit.         </div> | RW     |

## 34.6.4.3 Host Frame Number/Frame Remaining Time Register (USBHS\_HFNUM)

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |       |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|-------|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| 0x408  | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15    | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x00003FFF   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |       |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | FTREM        |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    | FRNUM |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Access | RO           |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    | RO    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| Bit   | Name  | Function             | Description                                                                                                                                                                                                                                                                        | Access |
|-------|-------|----------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 31:16 | FTREM | Frame time remaining | Indicates the remaining time of the current frame (in units of PHY clock counts). This field decrements by 1 for each PHY clock that passes. When the value reaches zero, this field reloads the value from the frame interval register and the module sends a new SOF on the USB. | RO     |
| 15:0  | FRNUM | Frame number         | When a new SOF is sent on the USB, the value of this field increments by 1, and it clears to zero when it reaches 0x3FFF.                                                                                                                                                          | RO     |

#### 34.6.4.4 Host Periodic Transmit FIFO/Queue Status Register (USBHS\_HPTXSTS)

This read-only register contains information about the free space in the periodic Tx FIFO and periodic transmit request queue.

| Offset | Bit Position |    |    |    |    |    |    |    |         |    |    |    |    |    |    |    |          |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |  |  |  |  |  |  |

### 34.6.4.5 Host All Channels Interrupt Register (USBHS\_HAINT)

When an event occurs on the channel, the host all-channel interrupt register interrupts the application using the host channel interrupt bit in the module interrupt register (the HCINT bit in USBHS\_GINTSTS). Each channel corresponds to one interrupt bit, with a maximum of 16 bits.

Bits in this register are also cleared when the application clears an interrupt via the corresponding host channel x interrupt register.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |       |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| 15:0  | HAINT    | Channel interrupt | Corresponding to Channel 15 to Channel 0: <ul style="list-style-type: none"> <li>0b0: No interrupt was generated on this channel</li> <li>0b1: An interrupt was generated on this channel</li> </ul> <div>  <b>Note</b><br/>           Each bit corresponds to one channel.         </div> | RO     |

### 34.6.4.6 Host All Channels Interrupt Mask Register (USBHS\_HAINTMSK)

The host all-channel interrupt mask register is used in conjunction with the host all-channel interrupt register to interrupt the application when an event occurs on the channel.

Each channel corresponds to 1 interrupt mask bit, up to 16 bits.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |        |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

### 34.6.4.7 Host Port Control and Status Register (USBHS\_HPRT)

This register is only available in host mode. Currently, the USBHS host only supports one port.

This register contains information related to the USB port, such as USB reset, enable, suspend, resume, connection status. The PENCHNG/PCDET bit in this register can trigger an application interrupt through the host port interrupt bit in the module interrupt register (HPRTINT bit in USBHS\_GINTST). When a port interrupt occurs, the application must read this register and clear the bit that caused the interrupt. The application must write a 1 to this bit to clear the interrupt.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |      |       |    |    |    |      |       |    |          |      |       |      |          |         |      |       |       |   |   |

#### 34.6.4.10 Host Channel x Interrupt Register (USBHS\_HCINTx) (x=0-15)

This register indicates the state of the channel when USB and AHB-related events occur. When the host channel interrupt bit (HCINT bit in USBHS\_GINTSTS) in the module interrupt register is set to 1, the application must read this register. Before performing a read operation on the register, the application must first read the host all-channel interrupt (USBHS\_HAINT) register to obtain the accurate channel number for the host channel x interrupt register. The application must clear the corresponding bits in this register to clear the corresponding bits in the USBHS\_HAINT and USBHS\_GINTSTS registers.

|------|---------|-------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 31:0 | DMAADDR | DMA address | This field stores the address of the memory used for DMA transfers when the host obtains data from the device endpoint or sends data to the device endpoint. This register is incremented at the end of each AHB transfer. | RW     |

### 34.6.5 USBHS Device Mode Register

The device mode registers affect the operation of the module in device mode. The device mode registers must not be accessed in host mode because the results are ambiguous.

#### 34.6.5.1 Device Configuration Register (USBHS\_DCFG)

This register configures the module into device mode after power-on, execution of certain control commands, or enumeration. Do not change this register after initial programming.

| 1   | SDIS   | Soft disconnect          | <p>The application uses this bit to signal the USBHS module to perform a soft disconnect. When this bit is set, the host will not see that the device is attached, and the device will not receive signals on the USB. The module remains disconnected until the application program clears this bit.</p> <ul style="list-style-type: none"> <li>0b0: Normal operation. Clearing this bit after a soft disconnect causes the host to receive a device connected event. After reconnecting the device, the USB host restarts device enumeration.</li> <li>0b1: Make the host receive a device disconnect event.</li> </ul> <p>At full speed, the minimum time for soft disconnection is specified as follows:</p> <ul style="list-style-type: none"> <li>Suspended state: the minimum time is 1ms+2.5μs</li> <li>Idle state: 2.5μs</li> <li>Non-idle or suspend state: 2.5μs</li> </ul> | RW     |
| 0   | RWUSIG | Remote wake-up signaling | When the application program sets this bit to 1, the module will initiate a remote wake-up signal to wake up the USB host. The application must set this bit to bring the module out of the suspended state. According to the USB2.0 specification, the application must clear this bit within 1ms to 15ms of setting it.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | RW     |

### 34.6.5.3 Device Status Register (USBHS\_DSTS)

This register indicates the status of the module when USB-related events occur. When an interrupt occurs, the endpoint information must be read from the device all-segment endpoint interrupt register (USBHS\_DAINTE).

When the idle state on the USB bus persists for 3ms, the module enters a suspend state. The module exits the suspend state under the following conditions: <ul style="list-style-type: none"> <li>Activity on the USB data lines.</li> <li>The application writes to the remote wakeup signal bit (RWUSIG bit in USBHS_DCTL) in the USBHS_DCTL register.</li> </ul> | RO     |

#### 34.6.5.4 Device IN Endpoint General Interrupt Mask Register (USBHS\_DIEPMSK)

This register is used in conjunction with the USBHS\_DIEPINTx registers of all endpoints to generate interrupts on each IN endpoint. By performing a write operation on the corresponding bit of this register, the IN endpoint interrupt in the USBHS\_DIEPINTx register can be masked. By default, all status interrupts are masked.

### 34.6.5.5 Device OUT Endpoint General Interrupt Mask Register (USBHS\_DOEPMSK)

This register works in conjunction with the individual USBHS\_DOEPINTx registers for all endpoints to generate interrupts on each OUT endpoint. OUT endpoint interrupts in the USBHS\_DOEPINTx registers can be masked by writing to the corresponding bit in this register. By default, all status interrupts are masked.

### 34.6.5.6 Device All Endpoints Interrupt Register (USBHS\_DAINR)

When a active event occurs on an endpoint, the USBHS\_DAINR register interrupts the application via the device OUT endpoint interrupt bit or device IN endpoint interrupt bit (OEPINT or IEPINT bits in USBHS\_GINTSTS, respectively) in the USBHS\_GINTSTS register. Each endpoint corresponds to one interrupt bit, with a maximum of 16 interrupt bits for both OUT and IN endpoints. Bidirectional endpoints will use the corresponding IN and OUT interrupt bits. When the application sets or clears the corresponding bit in the device endpoint x interrupt register (USBHS\_DIEPINTx/USBHS\_DOEPINTx), the corresponding bit in this register is also set or cleared.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |        |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

### 34.6.5.7 Device All Endpoints Interrupt Mask Register (USBHS\_DAINTRSK)

The USBHS\_DAINTRSK register is used in conjunction with the device endpoint interrupt register to interrupt the application when an event occurs on the device endpoint. However, the corresponding bit in the USBHS\_DAINTR register is still set to 1 for this interrupt.

### 34.6.5.16 Device IN Endpoint x Interrupt Register (USBHS\_DIEPINTx) (x=0-15)

This register indicates the status of the endpoint when USB and AHB related events occur. When the IN endpoint interrupt bit (IEPINT bit in USBHS\_GINTSTS) in the module interrupt register is set to 1, the application must read this register. Before the application can read this register, it must first read the device all-endpoint interrupt (USBHS\_DAINTE) register to obtain the correct endpoint number of the device endpoint x interrupt register. The application must clear the corresponding bit in this register in order to clear the corresponding bits in the USBHS\_DAINTE and USBHS\_GINTSTS registers.

### 34.6.5.17 Device IN Endpoint 0 Transfer Size Register (USBHS\_DIEPTSZ0)

The application must modify this register before enabling endpoint 0. After enabling endpoint 0 by setting the endpoint enable bit (EPENA in USBHS\_DIEPCTL0) in the device control endpoint 0 control register, the module modifies this register. The application can read this register only after the module has cleared the endpoint enable bit.

Non-zero endpoints use registers for endpoints 1-15.

| 6:0   | XFRSIZ   | Transfer size | Indicates the amount of data included in one data transfer for endpoint 0, in bytes. The module interrupts the application only after the application has transferred this data. The transfer size can be set to the endpoint's maximum packet size to break at the end of each packet.<br>The module decrements this field each time a packet from external memory is written to the TxFIFO. | RW     |

### 34.6.5.18 Device IN Endpoint x Transfer Size Register (USBHS\_DIEPTSIZE<sub>x</sub>) (x=1-15)

The application must modify this register before enabling the endpoint. After the endpoint is enabled via the endpoint enable bit (EPENA bit in USBHS\_DIEPCTL<sub>x</sub>) in the USBHS\_DIEPCTL<sub>x</sub> register, the module modifies this register. The application can only read this register after the module clears the endpoint enable bit.

| 27    | SNAK     | Set NAK          | Writing to this bit sets the NAK bit of the endpoint to 1.<br>With this bit, the application can control the sending of NAK handshake signals on the endpoint.<br>The module can also set this bit of the endpoint to 1 after the endpoint receives the SETUP packet.                                                  | RW     |
| 26    | CNAK     | Clear NAK        | Writing to this bit clears the NAK bit of the endpoint.                                                                                                                                                                                                                                                                | RW     |
| 25:22 | Reserved | Reserved         | -                                                                                                                                                                                                                                                                                                                      | -      |
| 21    | STALL    | STALL handshake  | The application can only set this bit when the endpoint receives a SETUP token, and the module clears it. If the NAK bit, global OUT NAK, and this bit are all set to 1, the STALL bit takes precedence. Regardless of how this bit is set, the module always responds to SETUP packets with an ACK handshake.         | RW     |
| 20    | SNPM     | Snoop mode       | This bit is used to configure the endpoint in listen mode. In listen mode, the module does not check the OUT packet for correctness before transferring it to the application memory.                                                                                                                                  | RW     |
| 19:18 | EPTYP    | Endpoint type    | Hardware setting is '0b00', indicating a control-type endpoint.                                                                                                                                                                                                                                                        | RO     |

| 15    | USBAEP   | USB active endpoint | Indicates whether this endpoint is active in the current configuration and interface. The module clears this bit to 0 for all endpoints except endpoint 0 when a USB reset is detected. After receiving the SetConfiguration and SetInterface commands, the application must program the endpoint register accordingly and set this bit to 1. | RO     |

| 10:0  | MPSIZ    | Maximum packet size | The application must program this field to the maximum packet size of the current logical endpoint. This value is in bytes.                                                                                                                                                                                                                   | RW     |

### 34.6.5.23 Device OUT Endpoint x Interrupt Register (USBHS\_DOEPINTx) (x=0-15)

This register indicates the status of the endpoint when USB and AHB related events occur. When the OUT endpoint interrupt bit (OEPINT bit in USBHS\_GINTSTS) in the USBHS\_GINTSTS register is set to 1, the application must read this register. Before the application can read this register, it must first read the USBHS\_DAIN register to obtain the correct endpoint number of the USBHS\_DOEPINTx register. The application must clear the corresponding bit in this register in order to clear the corresponding bits in the USBHS\_DAIN and USBHS\_GINTSTS registers.

| 6     | B2BSTUP  | Received consecutive SETUP packet         | Applicable only to control OUT endpoints. This bit indicates that this endpoint has received more than three consecutive SETUP packets. Writing 1 to this bit by software can also clear it.                                                                                                                       | RW     |
| 5     | Reserved | Reserved                                  | -                                                                                                                                                                                                                                                                                                                  | -      |
| 4     | OTEPDIS  | OUT token received when endpoint disabled | Applicable only to control OUT endpoints. Indicates that an OUT token was received when the endpoint was not yet enabled, generating an interrupt. Write 1 to clear by software.                                                                                                                                   | RW     |
| 3     | STUP     | SETUP phase done                          | Applicable only to control OUT endpoints. Indicates that the SETUP phase of the control endpoint has been completed and no more consecutive SETUP data packets is received in the current control transfer. On this interrupt, the application can decode the received SETUP packet. Write 1 to clear by software. | RW     |
| 2     | Reserved | Reserved                                  | -                                                                                                                                                                                                                                                                                                                  | -      |
| 1     | EPDISD   | Endpoint disabled interrupt               | This bit indicates that the endpoint has been disabled by the application. Write 1 to clear by software.                                                                                                                                                                                                           | RW     |

| Bit | Name | Function                     | Description                                                                                                                      | Access |
|-----|------|------------------------------|----------------------------------------------------------------------------------------------------------------------------------|--------|
| 0   | XFRC | Transfer completed interrupt | This field indicates that transfers set on this end-point have completed transfers on USB and AHB. Write 1 to clear by software. | RW     |

### 34.6.5.24 Device OUT Endpoint 0 Transfer Size Register (USBHS\_DOEPTSIZE0)

The application must modify this register before enabling endpoint 0. After enabling endpoint 0 by setting the endpoint enable bit (EPENA in USBHS\_DIEPCTL0) in the device control endpoint 0 control register, the module modifies this register. The application can read this register only after the module has cleared the endpoint enable bit.

Non-zero endpoints use registers for endpoints 1-15.

| 19    | PKTCNT   | Packet count       | The number of data packets that should be received in one transfer.<br>Before the endpoint is enabled, the software sets this bit. After the transmission starts, every time a data packet is received, the value of this field is automatically reduced.                                                                                                                                               | RW     |
| 18:7  | Reserved | Reserved           | -                                                                                                                                                                                                                                                                                                                                                                                                       | -      |
| 6:0   | XFRSIZ   | Transfer size      | Indicates the amount of data included in one data transfer for endpoint 0, in bytes. The module interrupts the application only after the application has transferred this data. The transfer size can be set to the endpoint's maximum packet size to break at the end of each packet.<br>The module decrements this field each time a packet is read from the Rx FIFO and written to external memory. | RW     |

### 34.6.5.25 Device OUT Endpoint x Transfer Size Register (USBHS\_DOEPTSIZx) (x=1-15)

The application must modify this register before enabling the endpoint. After the endpoint is enabled via the endpoint enable bit (EPENA bit in USBHS\_DOEPCTLx) in the USBHS\_DOEPCTLx register, the module modifies this register. The application can only read this register after the module clears the endpoint enable bit.

| 31:0 | DMAADDR | DMA address | <p>This bit contains the starting address of the external storage area when data is sent on the endpoint using DMA.</p> <div>  <b>Notice</b><br/>           For control endpoints, the storage area pointed to by this field is also used to store control OUT data packets and SETUP transaction data packets. When three or more SETUP data packets are received consecutively, the SETUP data packets in the memory are overwritten. This register is incremented for every AHB transfer. The application must set a double word aligned address.         </div> | RW     |

### 34.6.6 USBHS Clock Gating Control Register

Control HCLK and PHY clock by gating the clock control register to reduce power consumption.

#### 34.6.6.1 Clock Gating Control Register (USBHS\_GCCTL)

This register is available in both host mode and device mode.

The application program clears this bit when USB communication resumes.                                                                      | RW     |

## 35 USB2.0 Full-Speed Module (USBFS)

### 35.1 Introduction

USB full-speed (USBFS) controller provides a set of USB communication solutions for portable devices. The USBFS controller supports host mode and device mode, and a full-speed PHY is integrated inside the chip. In host mode, the USBFS controller supports full-speed (FS, 12Mbit/s) and low-speed (LS, 1.5Mbit/s) transceivers, while in device mode it only supports full-speed (FS, 12Mbit/s) transceivers. USBFS controller supports all four transmission modes defined by USB 2.0 protocol (Control transfer, Bulk transfer, Interrupt transfer, and Isochronous transfer). The USBFS controller supports LPM (Link Power Management) function.

The protocol is as follows:

- Universal Serial Bus Revision 2.0 Specification
- USB 2.0 Link Power Management Addendum Engineering Change Notice to the USB 2.0 specification, July 16, 2007
- Errata for USB 2.0 ECN: Link Power Management (LPM) - 7/2007

### 35.2 Features

#### 35.2.1 General Features

- Built-in on-chip USB2.0 full-speed PHY
- Supports host mode and device mode
- Supports FS SOF and low-speed "Keep-alive" tokens with the following functions:
  - ▶ SOF pulse pin output function
  - ▶ The SOF pulse can serve as an internal event source to trigger operations of modules such as TIMER and DMA.
  - ▶ Configurable frame period
  - ▶ Configurable frame end interrupt
- The module embeds DMA and supports software-configurable AHB burst transmission types
- Supports power-saving functions, such as USB suspend, stopping RAM clock, and stopping PHY domain clock
- Equipped with a dedicated 2.5KB RAM featuring advanced FIFO control
  - ▶ The RAM space can be partitioned into different FIFOs for flexible and efficient utilization of RAM
  - ▶ Each FIFO can store multiple data packets
  - ▶ Dynamic allocation of memory area
  - ▶ The FIFO size can be configured to non-power-of-two values for continuous memory unit utilization
- Within one frame, no application intervention is required to achieve maximum USB bandwidth
- The mode (Host Mode or Device Mode) can be automatically determined based on the ID line level

#### 35.2.2 Host Mode Features

- Host mode supports USB2.0 full-speed (FS, 12Mbit/s) and low-speed (LS, 1.5Mbit/s) transmissions
- The VBUS voltage needs to be generated by an external power supply chip
- Up to 16 host channels (Pipes) : Each channel can be dynamically reconfigured to support any type of USB transfer

- Built-in hardware scheduler capable of:
  - ▶ Store up to 8 interrupt plus isochronous transfer requests in a periodic hardware queue
  - ▶ Store up to 8 control and bulk transfer requests in a non-periodic hardware queue
- Manages a shared RX FIFO, a periodic TX FIFO, and a non-periodic TX FIFO to efficiently utilize USB data RAM

### 35.2.3 Device Mode Features

- Slave mode supports USB2.0 full-speed (FS, 12Mbit/s) transmission
- 1 bidirectional control endpoint 0
- 15 OUT endpoints, configurable to support bulk transfers, interrupt transfers, or isochronous transfers.
- 15 IN endpoints, configurable to support bulk transfers, interrupt transfers, or isochronous transfers.
- Contains 16 transmit FIFOs (one for each IN endpoint) and one receive FIFO (shared by all OUT endpoints)
- Supports remote wake-up function
- Supports soft disconnect function
- The VBUS PIN supports 5V withstand voltage

## 35.3 Functional Description

### 35.3.1 System Block Diagram

Figure 35-1 USBFS System Block Diagram

### 35.3.2 Pin Description

Table 35-1 USBFS Pin Description

| Pin Name      | Direction    | Applicable Mode | Corresponding Pins | Function Description                 |
|---------------|--------------|-----------------|--------------------|--------------------------------------|
| USBFS_VBUS    | Input        | Equipment       | PA9                | Power port, 5V withstand voltage     |
| USBFS_DP      | Input/Output | Host, device    | PA12               | Differential data D+ signal          |
| USBFS_DM      | Input/Output | Host, device    | PA11               | Differential data D-signal           |
| USBFS_DRVVBUS | Output       | Host            | PC9, PB8           | External power chip enable signal    |
| USBFS_ID      | Input        | Host            | PA10               | USB A-B device identification signal |
| USBFS_SOF     | Output       | Host, device    | PA8                | SOF output pulse signal              |

Since the USBFS\_DP and USBFS\_DM pins are multiplexed with universal GPIO, it is recommended to disable the digital function of the corresponding pins when using USBFS. The USBFS\_DP and USBFS\_DM functions are analog functions, independent of the associated PFSR register settings. For details, see the relevant description in the "Port Controller (GPIO) " chapter. In addition, when the USBFS function is not used, the digital function pin corresponding to the USBFS\_DP and USBFS\_DM pins consumes additional current when flipped.

### 35.3.3 Clock and Work Mode

The clock used by USBFS must be configured to 48MHz. This 48MHz clock is generated by the internal PLL circuit. The PLL clock source must select the external high speed oscillator. Before using the USBFS Block, the USBFS clock must be properly configured in the CMU Block.

USBFS can operate as either a host or device, and includes an on-chip full-speed PHY.

The pull-up and pull-down resistors are integrated inside the on-chip full-speed PHY, and USBFS can automatically select them based on the current mode and connection status.

During USBFS operation, the VCC voltage range is 3.0-3.63V.

### 35.3.4 Mode Decision

USBFS determines the current operating mode using the following two methods:

- Method 1: Automatic identification based on the status of USBFS\_ID line. When the USBFS\_ID line is detected at high level, the module works in the device mode. When the USBFS\_ID line is detected at low level, the module works in host status.
- Method 2: Force host/device mode. By setting the FDMOD or FHMOD bit in the USBFS\_GUSBCFG register to 1, the module will ignore the USBFS\_ID line level and forcibly worked in device or host mode.

### 35.3.5 Host Function

#### Function Introduction

When USBFS works in host mode, VBUS is the 5V power supply pin specified by the USB protocol. The internal PHY does not support 5V power supply, so an external USB power chip is required to power the device. USBFS\_DRVVBUS is used to enable the external USB power chip. The overcurrent detection of the external power supply chip can be implemented through the external interrupt IRQ of this MCU. In host mode, USBFS\_VBUS can be used as GPIO.

A typical USB host mode system architecture diagram is as follows:

Figure 35-2 USBFS Host Mode System Architecture Diagram

#### Host Port Power Supply

This MCU cannot output 5V to supply VBUS. To achieve this, a USB power supply chip or a basic power switch (if the circuit board provides 5V power) must be added externally to the microcontroller to drive the 5V VBUS line. The external power chip can be driven by any GPIO output or USBFS\_DRVVBUS. When

the application determines to use GPIO to control an external device for providing VBUS, the port power bit (USBFS\_HPRT.PWPR) in the host port control and status register must still be set to 1.

### Host Detects Device Connection and Disconnection

The USB device will be detected immediately after connection. The USBFS module will issue a host port interrupt signal, which is triggered by the device connection bit (USBFS\_HPRT.PCDET) in the host port control and status register.

A device disconnect event will trigger a disconnect detection interrupt (USBFS\_GINTSTS.DISCINT).

### Host Enumeration

After a device connection is detected, if a new device is connected, the host must initiate the enumeration process by sending a USB reset and configuration command to the new device.

The application sets the port reset bit (USBFS\_HPRT.PRST) in the host port control and status register to 1, maintaining this state for a minimum of 10ms and a maximum of 20ms, thereby driving the USB reset signal (single-ended zero) through the USB driver. The application calculates the duration of this process, then clears the port reset bit.

After the USB reset sequence is completed, the port enable/disable change bit (USBFS\_HPRT.PENCHNG) triggers a host port interrupt immediately, notifying the application that the enumerated device speed can be read from the port speed field (PSPD in USBFS\_HPRT) in the host port control and status register, and that the host has started driving SOF (FS) or Keep-alive tokens (LS). At this point the host is ready to enumerate the device by sending commands to the device.

### Host Suspend

The application suspends the USB bus by setting the port suspend bit (PSUSP in USBFS\_HPRT) in the host port control and status register to 1. The USBFS module stops sending SOF and enters suspend status.

The bus can exit suspend status through autonomous activity (remote wake-up) from a remote device. In this scenario, the remote wake-up signal will trigger a remote wake-up interrupt (USBFS\_GINTSTS.WKUPINT). The hardware automatically resets the port resume bit (USBFS\_HPRT.PRES) in the host port control and status register and drives the resume signal via USB autonomously. The application must time the resume window, then clear the port resume bit to exit the suspend status and restart SOF.

If the host initiates exit from suspend status, the application must set the port resume bit to 1 to activate the resume signaling on the host port, time the resume window, and finally clear the port resume bit.

### Host Channel

The USBFS module implements 16 host channels. Each host channel can be used for USB host transfers (USB pipes). The host can handle up to 8 transfer requests at the same time. If the application has more than 8 transfer requests pending, the host controller driver (HCD) must reassign the channel for unprocessed transfer requests after the channel is released from the previous task (i.e., upon receiving the transmission complete and channel halt interrupts).

Each host channel can be configured to support input/output and periodic/non-periodic transactions. Each host channel uses dedicated control (HCCHARx) register, transfer configuration (HCTSIZx) register/interrupt (HCINTx) register, and its associated interrupt mask register (HCINTMSKx).

#### Host Channel Control

The application can control the host channel through the host channel x characteristic register (HCCHARx) with the following settings:

- Channel enabled/disabled
- Set the target USB device speed: FS/LS
- Set the target USB device address
- Set the endpoint number on the target USB device for communication with this channel
- Sets the transfer direction on this channel: IN/OUT
- Set the type of USB transfer on this channel: control/bulk/interrupt/isochronous
- Set the maximum packet length of the device endpoint for communication with this channel
- Set the frame for periodic transfer: odd frame/even frame

#### Host Channel Transfer

The host channel transfer size register (HCTSIZx) allows applications to program the transmission size parameter and read the transfer status. The settings for this register must be completed before setting the channel enable bit to 1 in the host channel characteristics register. After enabling the endpoint, the packet count field immediately becomes read-only, while the USBFS module updates this field based on the current transmission status.

The following transfer parameters can be programmed:

- Transfer size in bytes
- The number of packets that make up the entire transfer size
- Initial Data PID

#### Host Channel Status/Interrupt

Host channel x interrupt register (HCINTx) indicates the endpoint status upon occurrence of USB and AHB related events. When the host channel interrupt bit (USBFS\_GINTSTS.HCINT) in the interrupt register is set to 1, the application must read these registers to obtain detailed information. Before reading these registers, the application must first read the host all channels interrupt (HCAINT) register to obtain the channel number of the host channel-x interrupt register. The application must clear the corresponding bit in this register to clear the corresponding bits in the HCAINT and GINTSTS registers. The USBFS\_HCINTMSKx register also provides mask bits for each interrupt source on every channel.

The host module provides the following status check and interrupt generation functions:

- Transfer complete interrupt, indicating both the application (AHB) and USB side have completed data transfer
- The channel stops due to transmission completion, USB transaction error, or a disable command issued by the application
- The associated transmit FIFO is half-empty or in full empty status (IN endpoint)
- ACK response received
- NAK response received
- STALL response received
- USB transaction error due to CRC check failure, timeout, bit stuffing error, or incorrect EOP
- Crosstalk error
- Frame overflow
- Error in toggling bit for data synchronization

## Host Scheduler

The host module has a built-in hardware scheduler that autonomously reorders and manages USB transaction requests issued by applications. At the start of each frame, the host first executes periodic (synchronous and interrupt) transactions, followed by non-periodic (control and bulk) transactions, to comply with the USB specification's guarantee of high priority for synchronous and interrupt transfers.

The host processes USB transactions through request queues (a periodic request queue and a non-periodic request queue). Each request queue can store up to 8 entries. Each entry represents a USB transaction request initiated by an application but not yet responded to, storing the IN or OUT channel number used to execute the USB transaction, along with other relevant information. The order in which USB transaction requests are written to the queue determines the execution sequence of transactions on the USB interface.

At the start of each frame, the host first processes the periodic request queue, then the non-periodic request queue. If at the end of the current frame, a pending synchronous or interrupt-type USB transfer transaction request scheduled for the current frame remains in suspend status, the host will issue an incomplete periodic transfer interrupt (USBFS\_GINTSTS.IPXFR). The USBFS module is responsible for managing both periodic and non-periodic request queues. Periodic transmit FIFO and queue status register (HPTXSTS) and non-periodic transmit FIFO and queue status register (HNPTXSTS) are both read-only registers. Applications can use them to read the status of each request queue. Including:

- Number (maximum 8) of currently available free entries in the periodic (non-periodic) request queue
- Periodic (non-periodic) TxFIFO (OUT transaction) currently available free space
- IN/OUT tokens, host channel number, and other status information

Since each request queue can store up to 8 USB transaction requests, the application can send host USB transaction requests to the scheduler in advance. The actual communication will appear on the USB bus no later than after the scheduler completes processing the 8 pending periodic transactions and 8 non-periodic transactions.

To issue a transaction request to the host scheduler (queue), the application must read the USBFS\_HPTXSTS.PTXQSAV or USBFS\_HNPTXSTS.NPTQSAV bit to ensure there is at least one available space in the periodic (non-periodic) request queue to store the current request.

## 35.3.6 Device Function

### Function Introduction

When the USBFS works in device mode, VBUS is the 5V power supply pin specified by the USB protocol and is a 5V withstand voltage pin. This module continuously monitors the VBUS line level status to connect or disconnect devices. The USBFS\_VBUS port must be connected to the VBUS power supply through a resistor of at least 1kΩ.

A typical USB device mode system block architecture diagram is as follows:

Figure 35-3 USBFS Device Mode System Architecture Diagram

### Power Supply State of Device

When the module detects that USBFS\_VBUS is at a high level, it enables the USB device to enter the power supply state. Then, USBFS automatically connects the DP pull-up resistor, signals a full-speed device connection to the host, and generates a session request interrupt (USBFS\_GINTSTS.VBUSINT), indicating entry into the powered state.

In addition, the USBFS\_VBUS input ensures the host provides a active VBUS level during USB operation. If a low level is detected on VBUS (e.g., caused by power supply interference or host port shutdown), USBFS will automatically disconnect.

Under power supply, the USBFS expects to receive a reset signal from the host. Other USB operations cannot be performed. Upon receiving the reset signal, a reset interrupt is immediately generated (USBFS\_GINTSTS.USBRSST). After the reset signal ends, an enumeration complete interrupt (USBFS\_GINTSTS.ENUMDNE) will be generated, and USBFS will then enter the default state.

### Device Default State

By default, USBFS expects to receive a SET\_ADDRESS command from the host. Other USB operations cannot be performed. When a active SET\_ADDRESS command is decoded on USB, the application writes the corresponding address value to the device address field (USBFS\_DCFG.DAD) in the device configuration register. The USBF immediately enters the address state and is ready to respond to host transactions using the configured USB address.

### Device Suspend State

The USBFS device continuously monitors USB activity. After the USB idle time reaches 3ms, an early suspend interrupt (USBFS\_GINTSTS.ESUSP) will be issued, and after 3ms, the suspend interrupt (USBFS\_GINTSTS.USBSUSP) will confirm the device enters suspend status. Then, the device suspend bit (USBFS\_DSTS.SUSPSTS) in the devices status register is automatically set to 1, and USBFS immediately enters the suspend status.

The device can exit the suspend status by itself. In this case, the application will set the remote wake-up signal bit (USBFS\_DCTL.RWUSIG) in the device control register to 1 and clear it within 1ms to 15ms.

However, if the device detects a resume signal from the host, it will generate a resume interrupt (USBFS\_GINTSTS.WKUPINT), and the device suspend bit will be automatically cleared.

### Device Soft-off

The power supply state can be exited via software using the soft disconnect function. Setting the soft disconnect bit (USBFS\_DCTL.SDIS) in the device control register to 1 removes the DP pull-up resistor. At

this point, even though the USB cable is not physically unplugged from the host port, the host will still detect a device disconnect and trigger an Interrupt.

## Device Endpoint

### Endpoint Type

The USBFS block implements the following USB endpoints:

- Control endpoint 0:
  - ▶ Bidirectional and handles only control messages
  - ▶ Use a separate set of registers to handle IN and OUT transactions
  - ▶ Dedicated control (USBFS\_DIEPCTL0/USBFS\_DOEPCTL0) register, transfer configuration (USBFS\_DIEPTSIZ0/USBFS\_DOEPSIZ0) register, and status interrupt (USBFS\_DIEPINTx/USBFS\_DOEPINT0) register. The available bit groups in the control and transmission size registers differ slightly from those in other endpoints
- 15 IN endpoints:
  - ▶ Each endpoint can be configured to support isochronous, bulk, or interrupt transfer types.
  - ▶ Each endpoint has dedicated control (USBFS\_DIEPCTLx) register, transfer configuration (USBFS\_DIEPTSIZx) register, and status interrupt (USBFS\_DIEPINTx) register
  - ▶ The device IN endpoint universal interrupt mask register (USBFS\_DIEPMSK) can be used to enable/disable the same type of interrupt sources on all IN endpoints (including EP0)
  - ▶ Supports interrupt for incomplete isochronous IN transfer (USBFS\_GINTSTS.IISOIXFR). This interrupt is triggered when at least one isochronous IN endpoint has an incomplete transfer in the current frame. This interrupt is triggered together with the periodic frame interrupt (USBFS\_GINTSTS/EOPF)
- 15 OUT endpoints:
  - ▶ Each endpoint can be configured to support isochronous, bulk, or interrupt transfer types.
  - ▶ Each endpoint has dedicated control (USBFS\_DOEPCTLx) register, transfer configuration (USBFS\_DOEPSIZx) register, and status interrupt (USBFS\_DOEPINTx) register.
  - ▶ The device OUT endpoint universal interrupt mask register (USBFS\_DOEPMSK) can be used to enable/disable the same type of interrupt sources on all OUT endpoints (including EP0).
  - ▶ Supports for incomplete isochronous OUT transfer interrupts (USBFS\_GINTSTS.INCOMPISOOOUT), which will trigger when at least one transfer on an isochronous OUT endpoint is incomplete in the current frame. This interrupt is triggered together with the periodic frame interrupt (USBFS\_GINTSTS/EOPF).

### Endpoint Control

Applications can control the endpoint through the device endpoint x IN/OUT control register (DIEPCTLx/DOEPCTLx) with the following operations:

- Endpoint enable/disable
- Enable endpoint in current configuration
- Set USB transfer type (Isochronous, Bulk, and Interrupt)
- Supported packet size setting
- Set the Tx-FIFO number associated with the IN endpoint
- Configure the desired data0/data1 PID for receiving or transmitting (applicable only to bulk/interrupt transfers)
- Set the corresponding odd/even frame for receive or transmit transactions (isochronous transfer only)

- The NAK Bit can be set to reply NAK to the host request regardless of the current FIFO status
- The STALL bit can be set to make the hardware respond with STALL to all host tokens for this endpoint
- The OUT endpoint can be configured in listen mode, where CRC checking is disabled for received data

### Endpoint Transfer

The device endpoint x transmission size register (DIEPTSIZE<sub>x</sub>/DOEPTSIZE<sub>x</sub>) allows the application to program transfer size parameters and read transfer status. The setting of this register must be completed before setting the endpoint enable bit in the endpoint control register to 1. After enabling the endpoint, these fields immediately become read-only, while the USBFS block updates them based on the current transmission status.

The following transfer parameters can be programmed:

- Transfer size in bytes
- The number of packets that make up the entire transfer

### Endpoint Status/Status

Device endpoint x interrupt register (DIEPINT<sub>x</sub>/DOEPINT<sub>x</sub>) indicates the endpoint status upon occurrence of USB and AHB related events. When the OUT endpoint interrupt bit or IN endpoint interrupt bit (corresponding to the USBFS\_GINTSTS.OEPINT/IEPINT) in the module interrupt register is set to 1, the application must read these registers to obtain detailed information. Before an application can read these registers, it must first read the device overall endpoint interrupt (USBFS\_DAINTE) register to obtain the endpoint number of the device endpoint x interrupt register. The application must clear the corresponding bit in this register to clear the corresponding bits in the DAINTE and GINTSTS registers.

The module provides the following status check and interrupt generation functions:

- Transfer complete interrupt, indicating to the application that both the AHB and the USB side have completed the data transfer
- Setup phase completed (only for OUT endpoints of control transfer type)
- The associated transmit FIFO is half-empty or in full-empty status (IN endpoint)
- A NAK reply has been sent to the host (IN endpoint for isochronous transfers only)
- IN token received while TxFIFO is empty (only for IN endpoints of bulk and interrupt transfer types)
- Received OUT token when endpoint is not enabled
- Babble error detected
- Application closes endpoint enable
- The application sets NAK to take effect for the endpoint (only applicable to IN endpoints of isochronous transfer type)
- Received more than 3 consecutive setup packets (only applicable to control-type OUT endpoints)
- Timeout detected (only for IN endpoints of control transfer type)

### 35.3.7 SOF Pulse Pin Output Function

In both host and device modes, USBFS can monitor, track, and configure SOF frames, and also features SOF pulse output functionality. The SOF pulse is output through the USBFS\_SOF pin, with a pulse width of 16 HCLK clock periods.

#### Host SOF

In host mode, the number of PHY clocks occurring between two consecutive SOF (FS) or keep-alive (LS) tokens can be programmed in the host frame interval register (HFIR), allowing the application to control the SOF frame period. An interrupt is generated at the start of frame (SOF bit in USBFS\_GINTSTS). The

current frame number and the remaining time until the next SOF can be tracked by the application in the host frame number register (HFNUM).

Using the SOFEN bit in USBFS\_SYCTLREG register, a SOF pulse signal with a width of 16 HCLK system clock periods can be output from the USBFS\_SOF pin simultaneously with any issued SOF token.

In addition, the SOF pulse can also serve as an internal event to trigger operations of external modules such as DMA transfers and TIMER counting.

### Device SOF

In device mode, each time the USB receives a SOF token, it will trigger a start-of-frame interrupt (SOF bit in USBFS\_GINTSTS). The corresponding frame number can be read from the device status register (FNSOF bit in USBFS\_DSTS). Using the SOFEN bit in the USBFS system control register USBFS\_SYCTLREG, a 16 HCLK system clock period SOF pulse signal can be generated and output on the USBFS\_SOF pin for external availability.

In addition, the SOF pulse can also work as an internal event to trigger operations of external modules such as DMA transfers and TIMER counting.

The periodic frame end interrupt (GINTSTS/EOPF) is used to notify the application when 80%, 85%, 90%, or 95% of the frame interval time has elapsed, depending on the periodic frame interval field (PFIVL bit in the USBFS\_DCFG) in the device configuration register. This function can be used to determine whether all isochronous communications for this frame are completed.

### 35.3.8 Power Consumption Control

When the USBFS module is not in use, the HCLK and PHY clocks of the USBFS module can be stopped through the CMU module to reduce power consumption.

When using the USB module, if the device USB session has not started or the device is not connected, power reduction techniques can be employed in the suspend status.

- Stop PHY clock (STPPCLK bit in USBFS\_GCCTL)

When the stop PHY clock bit in the clock gating control register is set to 1, most 48MHz internal clock domains in the USBFS full speed module are gated off by clock gating. Even if the application still provides a clock input, the dynamic power consumption caused by clock signal toggling in the block will be saved. Additionally, most units of the transceiver will be turned off, with only the portion responsible for detecting asynchronous recovery events or remote wake-up events remaining active.

- HCLK gating (GATEHCLK bit in USBFS\_GCCTL)

When the GATEHCLK bit in the clock gating control register is set to 1, most HCLK system clock domains inside the USBFS module are gated off by clock gating. Only the register read and write interface remains active. Even when the application still provides a clock input, the dynamic power consumption caused by clock signal toggling in the block is saved.

To save dynamic power consumption, the clock is only provided to the USB data FIFO when it is accessed by the USBFS module.

### 35.3.9 Dynamic Update of USBFS\_HFIR Register

In host mode, the USB module has the function to dynamically fine-tune the frame period, enabling synchronization between the external device and the SOF frame. If the USBFS\_HFIR register is modified within the current SOF frame, the SOF period will be adjusted accordingly in the next frame. For detailed specifications, refer to the figure below.

Figure 35-4 Schematic Diagram of USBFS Dynamic Update for USBFS\_HFIR Register

### 35.3.10 Data FIFO

The USBFS system features 2.5KB of dedicated RAM and employs an efficient FIFO control mechanism. In the USBFS module, the packet FIFO controller divides the RAM space into multiple TxFIFOs (Before USB transfer, the application pushes data into it for temporary storage) and a single Rx FIFO (The data received from the USB is briefly stored in it before being read by the application).

The number and organization of FIFOs built in RAM depend on the device's role. In device mode, a Tx FIFO is configured for each active IN endpoint. The FIFO size is software-configurable to better meet application requirements.

### 35.3.11 Host FIFO Architecture

Figure 35-5 Schematic Diagram of FIFO Architecture in Host Mode

### Host Rx FIFO

The host uses a receive FIFO to handle all periodic and non-periodic transactions. The FIFO serves as a receive buffer to store data received from USB (the data portion of received packets) until it is transferred to system memory. As long as there is space in the FIFO, data packets from the device's IN endpoint are received and stored sequentially. The status of each received data packet (including the host target channel, byte count, data PID, and checksum of the received data) is also stored in the FIFO. The size of the receive FIFO is configured in the receive FIFO size register (GRXFSIZ).

The single receive FIFO architecture enables the USB host to efficiently fill the receive data buffer:

- All IN configuration host channels share the same RAM buffer (shared FIFO)

- For any sequence of IN tokens driven by host software, the USBFS module can fill the receive FIFO up to its limit.

The application receives an RxFIFO non-empty interrupt whenever at least one data packet is available for reading in the RxFIFO. The application reads packet information from the receiving status and out-stack register and finally retrieves the data from the RxFIFO.

### Host TxFIFO

The host uses one transmit FIFO for all non-periodic (control and bulk) OUT transactions and the other transmit FIFO for all periodic (isochronous and interrupt) OUT transactions. FIFO serves as a transmit buffer to store data (transmit packets) for USB transmission. The periodic (non-periodic) TxFIFO size is configured in the host periodic (non-periodic) transmit FIFO size (HPTXFSIZ/HNPTXFSIZ) register.

The two TxFIFOs operate based on priority, with periodic communication having higher priority. Therefore, within one USB frame, periodic communication is processed first. At the start of the frame, the built-in host scheduler first processes the periodic request queue, then handles the non-periodic request queue.

The dual transmit FIFO architecture enables the USB host to separately optimize the management of periodic and non-periodic transmit data buffers:

- All host channels configured to support periodic (non-periodic) OUT transactions share the same RAM buffer (shared FIFO).
- For any sequence of OUT tokens driven by host software, the USBFS module can fill the periodic (non-periodic) transmit FIFO up to the limit.

The USBFS module issues a periodic TxFIFO empty interrupt (USBFS\_GINTSTS.PTXFE) whenever the periodic TxFIFO is half-empty or full-empty, depending on the value of the periodic Tx-FIFO empty level bit (USBFS\_GAHBCFG.PTXFELVL) in the AHB configuration register. As long as there is free space in both the periodic TxFIFO and the periodic request queue, the application can pre-write transmit data. The available space can be determined by reading the host periodic transmit FIFO and queue status register (HPTXSTS).

Whenever the non-periodic TxFIFO is half-empty or full-empty, the USBFS module generates a non-periodic TxFIFO empty interrupt (USBFS\_GINTSTS.NPTXFE), depending on the non-periodic TxFIFO empty level bit (USBFS\_GAHBCFG.TXFELVL) in the AHB configuration register. As long as there is free space in both the non-periodic TxFIFO and the non-periodic request queue, the application can write to transmit data. The available space of both can be checked by reading the host non-periodic transmit FIFO and queue status register (HNPTXSTS).

### 35.3.12 Device FIFO Architecture

Figure 35-6 Schematic Diagram of FIFO Architecture in USBFS Device Mode

#### Device Rx FIFO

USBFS device uses a single receive FIFO to receive data sent to all OUT endpoints. As long as there is free space in the Rx FIFO, the received data packets are sequentially filled into the Rx FIFO. In addition to active data, the received data packet status (including OUT endpoint target number, byte count, data PID, and activation of the received data) is also stored by the module. When no available space exists, the device responds with a NAK to the host transaction and triggers an interrupt on the addressed endpoint. The size of the receive FIFO is configured in the receive FIFO size register (GRXFSIZ).

The single receive FIFO architecture enables USB devices to more efficiently fill the receive RAM buffer:

- All OUT endpoints share the same RAM buffer (shared FIFO)
- For any host sequence OUT token, the USBFS module can fill the receive FIFO up to its limit

The application will continuously receive the Rx FIFO non-empty interrupt (USBFS\_GINTSTS.RXFNE) as long as at least one data packet is available for reading in the Rx FIFO. The application reads data packet information from the receive status read and out-stack register (GRXSTSP), and finally retrieves the corresponding data from the receive FIFO by reading the out-stack address associated with the endpoint.

## Device Tx FIFO

The module provides dedicated FIFO for each IN endpoint. The application configures the FIFO size for IN endpoint 0 through Device Endpoint 0 Transmit FIFO Size Register (USBFS\_DIEPTXF0), and configures the FIFO size for IN endpoint x through Device IN Endpoint Transmit FIFO Size Register (USBFS\_DIEPTXFx).

### 35.3.13 FIFO RAM Allocation

#### Host Mode

##### Receive FIFO RAM Allocation

Status information is written to the FIFO with each receive data packet. Therefore, at least (maximum data packet size/4) + 1 space must be allocated for receive data packets. If multiple isochronous channels are enabled, the allocated space for receiving continuous data packets must be at least twice the (maximum data packet size/4) + 1. Generally, the recommended space is twice the (maximum data packet size/4 + 1). This allows the USB to receive subsequent data packets while the previous packet is being transferred to the CPU.

The transmission completion status information and the last received data packet of this endpoint are written together into the FIFO. Therefore, a location must be allocated for this purpose.

When running in DMA mode, the DMA address register of each host channel will be stored in the FIFO. Therefore, one location must be reserved in the FIFO for each channel to store its address register.

##### Transmit FIFO RAM Allocation

The minimum RAM required for the host non-periodic transmit FIFO is the size of the largest data packet transmitted across all supported non-periodic OUT channels.

Typically, the recommended space is twice the maximum packet size, so that while USB is transmitting the current packet, AHB can fill the next packet into the transmit FIFO.

The minimum RAM required for the host to periodically send FIFO is the size of the largest data packet transmitted across all supported periodic OUT channels. If there is at least one isochronous OUT endpoint, the space must be at least twice the maximum packet size in this channel.

When running in DMA mode, the DMA address register of each host channel will be stored in the FIFO. Therefore, one location must be reserved in the FIFO for each channel to store its address register.

#### Device Mode

##### Receive FIFO RAM Allocation

The application shall allocate RAM for SETUP packets: 11 locations must be reserved in the receive FIFO to receive SETUP data packets on the control endpoint. The USBFS module will not write any other data to these bits reserved for SETUP data packets. A location will be allocated for the global OUT NAK.

Status information is written to the FIFO with each receive data packet. Therefore, at least (maximum packet size/4) + 1 space must be allocated for receive data packets. If multiple isochronous endpoints are enabled, the allocated space for receiving consecutive data packets must be at least twice the (maximum packet size/4) + 1. Generally, the recommended space is twice the (Maximum packet size/4 + 1). This allows the USB to receive subsequent data packets while the previous data packet is being transferred to the CPU.

The transfer completion status information and the last received data packet of this endpoint are pushed into the FIFO together. Normally, it is recommended to allocate one bit for each OUT endpoint.

##### Transmit FIFO RAM Allocation

The minimum RAM space required for each IN endpoint's transmit FIFO is the maximum data packet size of that specific IN endpoint.

### 35.3.14 System Performance

With a large-capacity RAM buffer, highly configurable FIFO size, 32-bit FIFO fast access via AHB push/pop registers, and especially the advanced FIFO control mechanism, optimal USB and system performance can be achieved. In fact, regardless of the current USB sequence, the USBFS can efficiently fill the available RAM space through this mechanism. With these features:

- The application has enough margin to calculate and correct the CPU load, thereby optimizing CPU bandwidth utilization:
  - ▶ The application can first accumulate a large amount of data to transmit, then send it out via USB.
  - ▶ Provides sufficient timing margin to read data from the receive FIFO.
- The USB module can keep working at full speed, that is, to provide the maximum full-speed bandwidth (as much hardware as possible to run automatically, and as little software as possible to participate)
  - ▶ The USB module can accumulate a large amount of sending data in advance at its disposal, enabling automatic management of USB data transmission.
  - ▶ There is ample free space in the receive buffer, which can be automatically filled with data from USB.

The USBFS module can efficiently fill the 2.5KB RAM buffer, and the 2.5KB transmit/receive data is sufficient to accommodate the data volume of a full speed frame. Therefore, the USB system can achieve maximum USB bandwidth within a single frame without application intervention.

### 35.3.15 Interrupt and Event

The USBFS interrupts include the following two types: the STOP mode wake-up interrupt USBFS\_WKUP and the USBFS global interrupt USBFS\_GLB.

#### ● USBFS\_WKUP Interrupt

The USBFS\_WKUP interrupt is used to wake up the system from STOP mode via USBFS\_DP or USBFS\_DM. The interrupt enable bit for this function is INT\_WUPEN.USF\_WUEN.

To wake up the system from STOP mode using USBFS, ensure the USBFS controller is in suspend status and configure the corresponding filter range and enable the filter function in the USBFS\_SYCTLREG register.

#### ● USBFS\_GLB Interrupt

USBFS\_GLB interrupt is the primary interrupt that software needs to handle. The global interrupt flag bit can be read from the USBFS\_GINTSTS Register.

Table 35-2 USBFS\_GLB Interrupt Event List

| Interrupt Flag | Description                               | Operating Mode | Internal Event Source |
|----------------|-------------------------------------------|----------------|-----------------------|
| WKUPINT        | Resume/Remote wake-up interrupt           | Host or device | -                     |
| VBUSVINT       | VBUS active interrupt                     | Device         | -                     |
| DISCINT        | Disconnect interrupt                      | Host           | -                     |
| CIDSCHG        | Connector ID line status change interrupt | Host or device | -                     |

| Interrupt Flag     | Description                                                      | Operating Mode | Internal Event Source |
|--------------------|------------------------------------------------------------------|----------------|-----------------------|
| PTXFE              | Periodic TxFIFO empty interrupt                                  | Host           | -                     |
| LPMINT             | LPM interrupt                                                    | Host or device | -                     |
| HCINT              | Host channel interrupt                                           | Host           | -                     |
| HPRTINT            | Host port interrupt                                              | Host           | -                     |
| DATAFSUSP          | Data acquisition suspend                                         | Device         | -                     |
| IPXFR/INCOMPISOOUT | Incomplete periodic transfer/Incomplete OUT isochronous transfer | Device         | -                     |
| IISOIXFR           | Incomplete IN isochronous transfer                               | Device         | -                     |
| OEPINT             | OUT endpoint interrupt                                           | Device         | -                     |
| IEPINT             | IN endpoint interrupt                                            | Device         | -                     |
| EOPF               | Periodic frame end interrupt                                     | Device         | -                     |
| ISOODRP            | Discard synchronization OUT data packet interrupt                | Device         | -                     |
| ENUMDNE            | Enumeration complete                                             | Device         | -                     |
| USBRST             | USB reset interrupt                                              | Device         | -                     |
| USBSUSP            | USB suspend interrupt                                            | Device         | -                     |
| ESUSP              | Early suspend interrupt                                          | Device         | -                     |
| GONAKEFF           | Global OUT NAK active interrupt                                  | Device         | -                     |
| GINAKEFF           | Global non-periodic IN NAK active interrupt                      | Device         | -                     |
| NPTXFE             | Non-periodic TxFIFO empty interrupt                              | Host           | -                     |
| RXFNE              | RxFIFO not empty interrupt                                       | Host or device | -                     |
| SOF                | Frame start interrupt                                            | Host or device | Yes                   |
| MMIS               | Mode mismatch interrupt                                          | Host or device | -                     |

## 35.4 Programming Module

### 35.4.1 Module Initialization

#### Context

The application must perform the module initialization sequence. For details on how to determine the mode, see [Mode Determination](#).

This section describes the initialization process after power-on of the USBFS controller. Whether working in host mode or device mode, the application must follow the initialization sequence. Initialize all module global registers based on the module configuration:

### Procedure

- Step1.** Program the following fields in the USBFS\_GAHBCFG register:
- Global interrupt mask bit GINTMSK=1
  - RxFIFO not empty (RXFNE bit in USBFS\_GINTSTS)
  - Periodic TxFIFO empty threshold
- Step2.** Program the following fields in the USBFS\_GUSBCFG register:
- FS timeout calibration field
  - USB turnaround time field
- Step3.** The software must unmask the following bits in the USBFS\_GINTMSK register:
- Mode mismatch interrupt mask
- Step4.** By reading the CMOD bit in USBFS\_GINTSTS, the software can determine whether the USBFS controller is operating in host mode or device mode.

## 35.4.2 Host Initialization

### Context

To initialize the module as the host, the application must perform the following steps:

### Procedure

- Step1.** Program USBFS\_GINTMSK.HPRTIM bit to 1 to unmask the interrupt.
- Step2.** Program the USBFS\_HCFG register to select full-speed host.
- Step3.** Program the PWPR bit in USBFS\_HPRT to 1 to supply VBUS to the USB bus.
- Step4.** Wait for the PCDET interrupt in USBFS\_HPRT. This indicates that a device is connected to the host port.
- Step5.** Program the PRST bit in USBFS\_HPRT to 1 to issue a reset signal on the USB bus.
- Step6.** Wait at least 10ms for allow the reset process to complete.
- Step7.** Program the PRST bit in USBFS\_HPRT to 0.
- Step8.** Wait for the PENCHNG interrupt in USBFS\_HPRT.
- Step9.** Read the PSPD bit in USBFS\_HPRT to obtain the enumeration speed.
- Step10.** Use the selected PHY clock and configure the HFIR register accordingly.
- Step11.** Program the FSLSPCS field in the USBFS\_HCFG register according to the device speed detected in Step 9. If the FSLSPCS is modified, a port reset must be performed.
- Step12.** Program the USBFS\_GRXFSIZ register to select the size of the receive FIFO.
- Step13.** Program the USBFS\_HNPTXFSIZ register to select the size and start address of the non-periodic transmit FIFO for non-periodic communication transactions.
- Step14.** Program the USBFS\_HPTXFSIZ register to select the size and start address of the periodic communication transmit FIFO for periodic communication transactions.

### Post Request

To communicate with the device, the system software must initialize and enable at least one channel.

## 35.4.3 Device Initialization

### Context

During power on or after switching from host mode to device mode, the application must perform the following steps to initialize the module as a device.

### Procedure

- Step1.** Program the following fields in the USBFS\_DCFG register:

- Device speed
- Non zero length status OUT handshake signal

**Step2.** Program the USBFS\_GINTMSK register to unmask the following interrupts:

- USB reset
- Enumeration complete
- Early suspend
- USB suspend
- SOF

**Step3.** Wait for the VBUSVINT interrupt in USBFS\_GINTSTS, indicating the power supply state is entered.

**Step4.** Wait for the USBRST interrupt in USBFS\_GINTSTS. This indicates that a reset signal has been detected on USB, and the reset process lasts approximately 10ms after receiving this interrupt.

**Step5.** Wait for the ENUMDNE interrupt in USBFS\_GINTSTS. This interrupt indicates the end of the reset process on USB. Upon receiving this interrupt, the application must read the USBFS\_DSTS register to determine the enumeration speed and perform the steps listed in the endpoint initialization on enumeration completion.

## Results

At this point, the device is ready to receive SOF data packets and perform control transfers on control endpoint 0.

## 35.4.4 DMA Mode

The USB uses the AHB host interface to fetch transmit data packet data (AHB to USB) and receive data updates (USB to AHB). The AHB host interface uses programmed DMA address (HCDMAx register in host mode and DIEPDMAx/DOEPDMAx registers in device mode) to access data buffers.

## 35.4.5 Host Programming Model

### 35.4.5.1 Channel Initialization

#### Context

The application must initialize one or more channels before communicating with the connected devices.

To initialize and enable the channel, the application must perform the following steps:

#### Procedure

**Step1.** Program the USBFS\_GINTMSK register to unmask the interrupt for the following bits:

- The non-periodic transmit FIFO for OUT transactions is empty (applicable when working at the pipeline transaction level and the programmed packet count field value is greater than 1).
- The non-periodic transmit FIFO for OUT transactions is half-empty (applicable when working at the pipeline transaction level and the programmed packet count field value is greater than 1).

**Step2.** Program the USBFS\_HAINTMSK register to enable the selected channel interrupt.

**Step3.** Program the USBFS\_HCINTMSK register to enable the interrupts related to communication transactions reflected in the host channel interrupt register.

- Step4.** Program the selected channel's USBFS\_HCTSIZx register to specify the total transmission size in bytes and the expected number of packets, including short packets. The application must program the PID field with the initial data PID (used for the first OUT transaction or expected to be obtained from the first IN transaction).
- Step5.** Program the selected channel's USBFS\_HCCHARx register to specify the endpoint features of the device, such as type, speed, direction, etc. (Only when the application is ready to send or receive data packets can the channel be enabled by setting the channel enable bit to 1.)

### 35.4.5.2 Channel Halted

The application can disable any channel by programming the USBFS\_HCCHARx registers by setting the CHDIS and CHENA bits to 1. This will cause the USBFS host to clear any previously issued requests on this channel (if any) and generate a channel stop interrupt. The application must wait for the CHH interrupt in USBFS\_HCINTx before reassigning the channel to other communication transactions. The USBFS host will not interrupt communication transactions already initiated on the USB.

Before disabling a channel, the application must ensure that there is at least one free space in the non-periodic request queue (when disabling non-periodic channels) or the periodic request queue (when disabling periodic channels). The application can clear the request queue by programming the USBFS\_HCCHARx register to set the CHDIS bit to 1 and clear the CHENA bit to 0 when the request queue is full (before disabling the channel). The application will disable the channel when any of the following conditions occur:

- STALL, TXERR, BBERR or DTERR interrupt received in USBFS\_HCINTx of IN or OUT channel. The application must be capable of receiving other interrupts (DTERR, Nak, Data, TXERR) from the same channel before receiving the channel stop signal.
- Received a DISCINT (disconnect device) interrupt in USBFS\_GINTSTS. (The application will disable all enabled channels).
- The application aborted the transfer before it could complete normally.

When in DMA mode, the application cannot stop an integral periodic transfer by writing to the register.

## 35.4.6 Device Programming Model

### 35.4.6.1 Endpoint Initialization on USB Reset

#### Procedure

- Step1.** Set the NAK bit to 1 for all OUT endpoints
- In USBFS\_DOEPCTLx, SNAK=1 (for all OUT endpoints)
- Step2.** Unmask the following interrupt bits
- In USBFS\_DAINTRSK, INEP0=1 (control 0 IN endpoint)
  - In USBFS\_DAINTRSK, OUTEP0=1 (control 0 OUT endpoint)
  - In DOEPMSK, STUP=1
  - In DOEPMSK, XFRC=1
  - In DIEPMSK, XFRC=1
  - In DIEPMSK, TOC=1
- Step3.** Configure data FIFO RAM for each FIFO
- Program the USBFS\_GRXFSIZ register to enable receiving OUT data and setup data for control transfers. This register must be at least equal to 1 maximum packet size for control endpoint 0 + 2 words (for control OUT packet status) + 10 words (for SETUP packet).

- Program the USBFS\_TX0FSIZ register (depending on the selected FIFO number) to enable transmit control IN data. The register must be at least equal to 1 maximum packet size of control endpoint 0.

**Step4.** Program the following fields in the endpoint-related register to enable control OUT endpoint 0 to receive SETUP packets

- In USBFS\_DOEPTSIZE0, STUPCNT=3 (receives up to 3 consecutive SETUP packets)

### Results

At this point, all initialization work required for receiving SETUP packets is completed.

### 35.4.6.2 Endpoint Initialization Upon USB Enumeration Completion

#### Procedure

- Step1.** Upon enumeration completion interrupt (ENUMDNE in USBFS\_GINTSTS), read the USBFS\_DSTS register to determine the device's enumeration speed.
- Step2.** Program the MPSIZ field in USBFS\_DIEPCTL0 to set the maximum packet size. This step configures control endpoint 0. The maximum packet size of the control endpoint depends on the enumeration speed.

### Results

At this point, the device is ready to receive SOF packets and is configured to perform control transfers on control endpoint 0.

### 35.4.6.3 Endpoint Initialization Upon Receiving the SetAddress Command

#### Context

This section describes the operations that the application must perform when receiving a SetAddress command in the SETUP packet.

#### Procedure

- Step1.** Program the USBFS\_DCFG register using the device address received in the SetAddress command.
- Step2.** Program the module to issue an IN data packet during the status phase.

### 35.4.6.4 Endpoint Initialization Upon Receiving SetConfiguration/SetInterface Command

#### Context

This section describes the operations that the application must perform upon receiving a SetConfiguration or SetInterface command in the SETUP packet.

#### Procedure

- Step1.** Upon receiving the SetConfiguration command, the application must program the endpoint registers to configure them using the features of active endpoints in the new configuration.
- Step2.** Upon receiving the SetInterface command, the application must program the endpoint register of the endpoint specified by the command.
- Step3.** Endpoints that were active in previous configurations or other settings become inactive in new configurations or other settings. These inactive endpoints must be disabled.
- Step4.** Use the USBFS\_DAINMSK register to enable interrupts for active endpoints and mask interrupts for inactive endpoints.
- Step5.** Set up data FIFO RAM for each FIFO.
- Step6.** After configuring all required endpoints, the application must program the module to transmit IN packets for the status stage.

## Results

At this point, the device module is ready to receive and transmit any type of data packet.

### 35.4.6.5 Endpoint Activation

#### Context

This section describes the steps required to activate a device endpoint or configure an existing device endpoint as a new type.

#### Procedure

- Step1.** In the USBFS\_DIEPCTLx register (for IN or bidirectional endpoints) or USBFS\_DOEPCTLx register (for OUT or bidirectional endpoints), program the features of the desired endpoint in the following fields.
- Maximum packet size
  - USB active endpoint bit set to 1
  - Endpoint initial data synchronization bit (for interrupt and bulk endpoints)
  - Endpoint type
  - TxFIFO number
- Step2.** After the endpoint is enabled, the module starts decoding tokens sent to the endpoint and replies with a active handshake signal if the received token is enabled.

### 35.4.6.6 Endpoint Disabled

#### Context

This section describes the steps required to disable an existing endpoint.

#### Procedure

- Step1.** To disable an endpoint, clear the USB active endpoint bit in the USBFS\_DIEPCTLx register (for IN or bidirectional endpoints) or the USBFS\_DOEPCTLx register (for OUT or bidirectional endpoints).
- Step2.** When an endpoint is disabled, the module ignores tokens sent to it, causing a USB timeout.

## 35.5 Operational Module

### 35.5.1 SETUP and OUT Data Transmission

This section describes the internal data flow and application operation steps during data OUT transfers and SETUP transactions.

#### Packet Reading

This section describes how to read data packets (OUT and SETUP data packets) from the receive FIFO.

1. When the RXFNE interrupt (USBFS\_GINTSTS register) is captured, the application must read the receive status pop up register (USBFS\_GRXSTSP).
2. The application can mask the RXFNE interrupt (in USBFS\_GINTSTS) by writing RXFNE=0 (in USBFS\_GINTMSK) until it reads the data packet from the receive FIFO.
3. If the byte counting of the received packet is not 0, pop up these data from the receive data FIFO and store them in memory. If the byte counting of the received packet is 0, no data will be popped from the receive data FIFO.
4. The packet status read from the receive FIFO has the following states:
  - Global OUT NAK:  
PKTSTS=Global OUT NAK, BCNT=0x000, the values of EPNUM and DPID are irrelevant.  
These data indicate that the global OUT NAK bit has taken effect.
  - SETUP packet:  
PKTSTS=SETUP, BCNT=0x008, EPNUM=Control EP number, DPID=D0. These data indicate that SETUP packets received on the specified endpoint can now be read from the receive FIFO.
  - Establishment phase completed:  
PKTSTS=Setup phase complete, BCNT=0x0, EPNUM=Control EP number, DPID value is irrelevant.  
This data indicates that the setup phase of the specified endpoint is complete and the data phase has been initiated. After this status entry pops from the receive FIFO, the module will generate a setup interrupt on the corresponding control OUT endpoint.
  - OUT packet:  
PKTSTS=DataOUT, BCNT=Size of received OUT data packet (BCNT: 0-1024), EPNUM=Endpoint number of the received data packet, DPID=Actual data PID.
  - Data transmission complete:  
PKTSTS=OUT data transmission complete, BCNT=0x0, EPNUM=OUT EP number that completed data transmission, DPID value is irrelevant.  
This data indicates the completion of OUT data transmission at the specified OUT endpoint. After this status entry pops from the receive FIFO, the module will trigger a "Transmission Complete" interrupt on the designated OUT endpoint.
5. After popping data from the receive FIFO, the RXFNE interrupt must be unmasked (USBFS\_GINTSTS).
6. Each time the application detects an RXFNE interrupt in USBFS\_GINTSTS, steps 1 through 5 will be repeated. Reading an empty receive FIFO may result in undefined module behavior.

#### SETUP Transaction

Describe the block's method for handling SETUP packets and the sequence for application processing of SETUP transactions.

#### Application Requirements:

1. To receive a SETUP packet, the control OUT endpoint STUPCNT field (USBFS\_DOEPTSIZE) must be programmed to a non-zero value. If the application programs the STUPCNT field to a non-zero value, the module will receive the SETUP packet and write it to the receive FIFO, regardless of the NAK status and the EPENA bit setting in USBFS\_DOEPCTL. For each SETUP packet received by the control endpoint, the STUPCNT field decrements. If the STUPCNT field is not programmed to the appropriate value before receiving the SETUP packet, the module can still receive the SETUP packet and decrement the STUPCNT field. However, the application may not be able to determine the correct number of SETUP packets received during the setup phase of the control transmission.
  - In USBFS\_DOEPTSIZE, STUPCNT=3
2. The application must always allocate some additional space in the receive data FIFO to accommodate up to three consecutive SETUP packets on the control endpoint.
  - Reserved space of 10 words. The first SETUP packet requires 3 words, the "Setup Phase Complete" status double-word requires 1 word, and an additional 6 words are needed to store two extra SETUP packets.
  - Each SETUP packet requires 3 words to store 8 bytes of SETUP data and 4 bytes of SETUP status. The module will reserve these spaces in the receive FIFO.
  - This FIFO is exclusively used for storing SETUP packets and will never utilize this space for data packets.
3. The application must read 2 words of SETUP data packet from the receive FIFO.
4. The application must read and discard the "Establishment Phase Complete" status word from the receive FIFO.

#### Internal Data Flow:

1. Upon receiving a SETUP packet, the module writes the received data into the receive FIFO without checking the available space in the receive FIFO, regardless of the endpoint's NAK and STALL bit settings.
  - The module internally sets the IN NAK and OUTNAK bits of the control IN/OUT endpoints that receive the SETUP packet to 1.
2. For each SETUP packet received over USB, the module writes 3 words of data into the receive FIFO and decrements the STUPCNT field by 1.
  - The first word contains internal control information used by the module.
  - The second word contains the first 4 bytes of the SETUP command.
  - The third word contains the last 4 bytes of the SETUP command.
3. When the setup phase ends and the data IN/OUT phase starts, the block writes a status entry ("Setup Phase Complete" word) into the receive FIFO, indicating the setup phase is complete.
4. On the AHB side, the SETUP packet is read by the application.
5. When the application pops the "Setup Phase Complete" word from the receive FIFO, the module will interrupt the application using the STUP interrupt (USBFS\_DOEPINT), indicating that it can process the received SETUP packet.
  - The module will clear the endpoint enable bit of control OUT endpoint.

#### Application Programming Sequence:

1. Program the USBFS\_DOEPTSIZE register.
  - STUPCNT=3
2. Wait for the RXFNE interrupt (USBFS\_GINTSTS) and read the data packet from the receive FIFO.
3. The STUP interrupt trigger (USBFS\_DOEPINT) indicates the successful completion of SETUP data transmission.

- When this interrupt occurs, the application must read the USBFS\_DOEPTSIZE register to determine the number of received SETUP packets and process the last received SETUP packet.

#### Processing More Than Three Consecutive SETUP Packets:

According to the USB2.0 specification, the host typically does not send more than three consecutive SETUP packets to the same endpoint during SETUP packet errors. However, the USB 2.0 specification does not limit the number of consecutive SETUP packets that the host can send to the same endpoint. When this occurs, the USBFS controller will generate an interrupt (B2BSTUP in USBFS\_DOEPINTx).

### Set Global OUT NAK to 1

#### Internal Data Flow:

1. If the application sets the global OUT NAK (SGONAK bit in USBFS\_DCTL) to 1, the module will stop writing any data other than SETUP packets to the receive FIFO. Regardless of the available space size in the receive FIFO, the device will respond with a NAK to asynchronous OUT tokens sent by the host, while directly ignoring synchronous OUT data packets.
2. The module writes the global OUT NAK to the receive FIFO. The application must reserve sufficient space for this.
3. When the application pops the global OUT NAK word from the receive FIFO, the block sets the GONAKEFF interrupt (USBFS\_GINTSTS) to 1.
4. When the application detects this interrupt, it will assume the module is in global OUT NAK mode. The application can clear this interrupt by clearing the SGONAK bit in USBFS\_DCTL.

#### Application Programming Sequence:

1. To stop receiving any type of data into the receive FIFO, the application must program the following fields to set the global OUT NAK bit to 1.
  - In USBFS\_DCTL, SGONAK=1
2. Wait for the GONAKEFF interrupt in USBFS\_GINTSTS. Once triggered, this interrupt indicates that the module has stopped receiving any type of data except SETUP packets.
  - If the application has set the SGONAK bit in USBFS\_DCTL to 1, the application can receive active OUT packets before the module generates a GONAKEFF interrupt (USBFS\_GINTSTS).
3. Applications can temporarily mask this interrupt by writing to the GINAKEFFM bit in the USBFS\_GINTMSK register.
  - In the USBFS\_GINTMSK register, GINAKEFFM=0.
4. When the application is ready to exit the global OUT NAK mode, the SGONAK bit in USBFS\_DCTL must be cleared. This operation also clears the GONAKEFF interrupt (USBFS\_GINTSTS).
  - In CGONAK, USBFS\_DCTL=1
5. If the application has previously masked this interrupt, the interrupt must be unmasked as follows:
  - In GINTMSK, GINAKEFFM=1

### Disable the enabled OUT endpoint

The application must disable the enabled OUT endpoint using the following sequence.

#### Application Programming Sequence:

1. Before disabling any OUT endpoint, the application must enable the global OUT NAK mode in the module.
  - In USBFS\_DCTL, SGONAK=1
2. Wait for the GONAKEFF interrupt (USBFS\_GINTSTS)
3. Disable the OUT endpoint by programming the following fields:

- In USBFS\_DOEPCTLx, EPDIS=1
  - In USBFS\_DOEPCTLx, SNAK=1
4. Wait for the EPDISD interrupt (USBFS\_DOEPINTx), which indicates that the OUT endpoint has been completely disabled. When an EPDISD interrupt is triggered, the module will also clear the following bits:
    - In USBFS\_DOEPCTLx, EPDIS=0
    - In USBFS\_DOEPCTLx, EPENA=0
  5. The application must clear the global OUT NAK bit to start receiving data from other OUT endpoints that are not disabled.
    - In USBFS\_DCTL, SGONAK=0

### Universal Asynchronous OUT Data Transmission

This section describes a general asynchronous OUT data transfer (control, bulk, or interrupt).

#### Application Requirements:

1. Before establishing an OUT transfer, the application must allocate a buffer in memory to hold all the data to be received as part of the OUT transfer.
2. For OUT transfer, the transfer size field in the endpoint's transfer size register must be a multiple of the endpoint's maximum packet size (and word-aligned).
  - $\text{Transfer Size}[\text{EPNUM}] = n \times (\text{MPSIZ}[\text{EPNUM}] + 4 - (\text{MPSIZ}[\text{EPNUM}] \bmod 4))$
  - $\text{Packet Count}[\text{EPNUM}] = n$
  - $n > 0$
3. When an OUT endpoint interrupt occurs, the application must read the endpoint's transfer size register to calculate the amount of active data in memory. The received active data amount may be less than the programmed transfer size.
  - $\text{Active data amount in memory} = \text{Initial transfer amount set by application program} - \text{remaining transfer amount after module update}$
  - $\text{Number of received USB data packets} = \text{Initial number of packets set by application} - \text{remaining number of packets after module update}$

#### Internal Data Flow:

1. The application must set the transfer size and packet count fields in the endpoint-related register, clear the NAK bit, and enable the endpoint to receive data.
2. After the NAK bit is cleared, the module starts to receive data and writes the data into the receive FIFO (as long as there is space in the receive FIFO). For each data packet received over USB, the packet and its status are written to the receive FIFO. Each packet (either a packet with data volume reaching the maximum packet size or a short packet) written to the receive FIFO will decrement the packet count field of this endpoint by 1.
  - If the received packet has an inactive CRC, it is automatically cleared from the receive FIFO.
  - After replying with an ACK for the data packet on USB, the module discards the non-isochronous OUT packet retransmitted by the host due to undetected ACK. The application will not detect multiple consecutive OUT packets on the same endpoint with identical data PIDs. In this case, the packet count does not decrement.
  - If there is no space in the receive FIFO, isochronous or asynchronous packets will be ignored and not written into the receive FIFO. In addition, an asynchronous OUT token will receive a NAK handshake response.

- In all three scenarios mentioned above, the packet count will not decrement as no data is written to the receive FIFO.
3. When the packet count becomes 0 or a short packet is received on the endpoint, the NAK bit of that endpoint will be set to 1. When the NAK bit is set to 1, both synchronous and asynchronous data packets will be ignored and not written into the receive FIFO. Additionally, asynchronous OUT tokens will receive a NAK handshake response.
  4. After data is written to the receive FIFO, the application will read data from the receive FIFO and write it to external storage, one packet at a time, endpoint by endpoint.
  5. After writing each data packet to the external storage via AHB, the endpoint's transmission size is automatically decremented by the size of the data packet.
  6. Under the following conditions, the OUT data transmission completion status of the OUT endpoint will be written to the receive FIFO:
    - Transfer size is 0 and packet count is 0
    - The last OUT data packet written to the receive FIFO is a short packet (Packet size: 0 to maximum packet size-1)
  7. When the application pops this status entry (OUT data transfer completed) and generates a transfer completed interrupt for this endpoint, it also clears the endpoint enable bit.

#### Application Programming Sequence:

1. Program the USBFS\_DOEPTSIZE register using the transfer size and corresponding packet count.
2. Program the USBFS\_DOEPCTL register using endpoint features, and set the EPENA and CNAK bits to 1.
  - In USBFS\_DOEPCTL, EPENA=1
  - In USBFS\_DOEPCTL, CNAK=1
3. Wait for the RXFNE interrupt (in USBFS\_GINTSTS) and read the data packet from the receive FIFO.
  - This step can be repeated multiple times, depending on the transfer size.
4. Trigger the XFRC interrupt (USBFS\_DOEPINT) to indicate the successful completion of an asynchronous OUT data transmission.
5. Read the USBFS\_DOEPTSIZE register to determine the active data amount.

#### Universal Synchronous OUT Data Transmission

This section describes regular synchronous OUT data transmission.

#### Application Requirements:

1. All application requirements for asynchronous OUT data transmissions apply equally to synchronous OUT data transmission
2. For synchronous OUT data transmissions, the transmission size and packet count fields must always be set to the number of packets corresponding to the maximum packet size receivable in a single frame. Synchronous OUT data transmission transactions must be completed within a single frame.
3. Before the periodic frame ends (EOPF interrupt in USBFS\_GINTSTS), the application must read all synchronous OUT packets (data entries and status entries) from the receive FIFO.
4. To receive data in the next frame, a synchronous OUT endpoint must be enabled after EOPF (USBFS\_GINTSTS) and before SOF (USBFS\_GINTSTS).

#### Internal Data Flow:

1. The internal data flow of synchronous OUT endpoints is essentially the same as that of asynchronous OUT endpoints, with minor differences.

2. When enabling a synchronous OUT endpoint by setting the endpoint enable bit to 1 and clearing the NAK bit, the corresponding even/odd frame bit must also be set to 1. The module will receive data from a specific frame on the synchronized OUT endpoint only when the following conditions are met:
  - EONUM (in USBFS\_DOEPCTLx)=FNSOF[0] (in USBFS\_DSTS)
3. When the application reads a complete synchronous OUT packet (data and status) from the receive FIFO, the module updates the RXDPID field in USBFS\_DOEPTSIZx based on the data PID of the last synchronous OUT packet read from the receive FIFO.

#### Application Programming Sequence:

1. Program the USBFS\_DOEPTSIZx register using the transmission size and corresponding packet count.
2. Program the USBFS\_DOEPCTLx register using endpoint features, and set the endpoint enable bit, clear NAK bit, and odd/even frame bit to 1.
  - EPENA1
  - CNAK=1
  - EONUM=(0: Even/1: Odd)
3. Wait for the RXFNE interrupt (in USBFS\_GINTSTS) and read the data packet from the receive FIFO.
  - This step can be repeated multiple times, depending on the transfer size.
4. XFRC interrupt (in USBFS\_DOEPINTx) indicates the completion of a synchronous OUT data transmission. This interrupt does not necessarily indicate that the data in memory is enabled.
5. For synchronous OUT transfers, the application may not always detect this interrupt. Instead, the application may detect the IISOXFRM interrupt in USBFS\_GINTSTS.
6. Read the USBFS\_DOEPTSIZx register to determine the received transmission size and verify the activity of the received data within the frame. The application shall consider the received data in memory as active only when one of the following conditions is met:
  - RXDPID=D0 (in USBFS\_DOEPTSIZx) and the number of active USB data packets received=1
  - RXDPID=D1 (in USBFS\_DOEPTSIZx) and the number of active USB data packets received=2
  - RXDPID=D2 (in USBFS\_DOEPTSIZx) and the number of active USB data packets received=3

The number of USB packets receiving active data=Initial packet count programmed by the application-remaining packet count after module update.

The application can discard inactive packets.

#### Incomplete Synchronous OUT Data Transmission

This section describes the application programming sequence when packet loss occurs in synchronous OUT data packets.

##### Internal Data Flow:

1. For synchronous OUT endpoints, the XFRC interrupt (in USBFS\_DOEPINTx) may not always be triggered. If the module discards the synchronized OUT data packet, the application may fail to detect the XFRC interrupt (USBFS\_DOEPINTx) under the following conditions:
  - When the receive FIFO cannot accommodate a complete ISO OUT packet, the module will discard the received ISO OUT data.
  - The received synchronization OUT packet has a CRC error.
  - The module received a corrupted synchronization OUT token.
  - The application reads data from the receive FIFO at a very slow speed.
2. If the block detects a periodic frame end before the transfer completion of all synchronous OUT endpoints, it will trigger an incomplete synchronous OUT data interrupt (IISOXFRM in USBFS\_GINTSTS),

indicating that at least one synchronous OUT endpoint did not trigger an XFRC interrupt (in USBFS\_DOEPINTx). At this time, endpoints with unfinished transfers remain enabled, but there are no ongoing active transfers on this USB endpoint.

#### Application Programming Sequence:

1. Hardware triggers the IISOXFRM interrupt (USBFS\_GINTSTS) indicating that at least one synchronous OUT endpoint has an incomplete transfer in the current frame.
2. If this occurs due to incomplete reading of synchronous OUT data from the endpoint, the application must ensure all synchronous OUT data (including data entries and status entries) are first read from the receive FIFO before proceeding with further processing.
  - After reading all data from the receive FIFO, the application can detect the XFRC interrupt (USBFS\_DOEPINTx). In this case, the application must re-enable the endpoint to receive synchronous OUT data in the next frame.
3. When the application receives the IISOXFRM interrupt (in USBFS\_GINTSTS), it must read the control registers (USBFS\_DOEPCTLx) of all synchronous OUT endpoints to determine which endpoints have incomplete transmission in the current frame. When both of the following conditions are met simultaneously, it indicates that the endpoint transfer is incomplete:
  - EONUM bit (in USBFS\_DOEPCTLx)=FNSOF[0] (in USBFS\_DSTS)
  - EPENA=1 (in USBFS\_DOEPCTLx)
4. Before detecting the SOF interrupt (in USBFS\_GINTSTS), the previous operation must be fully completed to ensure the current frame number has not changed.
5. For synchronous OUT endpoints with incomplete transmission, the application must discard the data in memory and disable the endpoint by setting the EPDIS bit in USBFS\_DOEPCTLx to 1.
6. Wait for the EPDIS interrupt (in USBFS\_DOEPINTx), and enable the endpoint to receive new data in the next frame.
  - Since the module may require some time to disable the endpoint, the application may fail to receive data in the next frame after detecting inactive synchronization data.

#### Disable Asynchronous OUT Endpoint

This section describes how the application can stop an asynchronous endpoint.

1. Place the module in global OUT NAK mode.
2. Disable the required endpoint
  - When disabling an endpoint, please set STALL=1 (in USBFS\_DOEPCTL) instead of setting the SNAK bit to 1 in USBFS\_DOEPCTL. The priority of the STALL bit is always higher than that of the NAK bit.
3. When the application no longer needs the endpoint to respond with a STALL handshake, the STALL bit (in USBFS\_DOEPCTLx) must be cleared to zero.
4. If an application receives a SetFeature.Endpoint Halt or ClearFeature.Endpoint Halt command from the host to set or clear the STALL state of an endpoint, it must set the STALL bit to 1 or clear it on the control endpoint before initiating the status phase transfer.

### 35.5.2 IN Data Transmission

#### Packet Write

This section describes how the application writes data packets to the endpoint FIFO when the dedicated transmit FIFO is enabled.

1. The application can choose between polling mode or interrupt mode.

- In polling mode, the application monitors the status of the endpoint transmit data FIFO by reading the USBFS\_DTXFSTSx register to determine whether there is sufficient space in the data FIFO.
  - In interrupt mode, the application waits for the TXFE interrupt (in USBFS\_DIEPINTx), then reads the USBFS\_DTXFSTSx register to determine if there is sufficient space in the data FIFO.
  - To write a single non-zero length packet, there must be sufficient space in the data FIFO to accommodate the entire packet.
  - To write a zero length packet, the application cannot check the FIFO space.
2. If one of the above methods is used, when the application determines there is sufficient space to write transmit data packets, the application must first perform the corresponding write operation to the endpoint control register before writing data to the data FIFO. Typically, the application must perform a read-modify-write operation on the USBFS\_DIEPCTLx register to avoid modifying other contents in the register while setting the endpoint enable bit to 1.  
If sufficient space is available, the application can write multiple data packets for the same endpoint into the transmit FIFO. For periodic IN endpoints, the application can only write multiple data packets within a single frame at a time. The application will only write all packets to be sent in the next frame after the previous frame's communication transaction has completed.

### Set IN Endpoint NAK to 1

#### Internal Data Flow:

1. When the application sets the IN NAK of a specific endpoint to 1, the module will stop data transmission on that endpoint, regardless of whether data is available in the endpoint's transmit FIFO.
2. The asynchronous endpoint receives the IN token and replies with a NAK handshake response.
  - The synchronous endpoint receives an IN token and returns a zero length data packet.
3. The module triggers the INEPNE (IN endpoint NAK active) interrupt in USBFS\_DIEPINTx in response to the SNAK bit in USBFS\_DIEPCTLx.
4. When the application detects this interrupt, it will consider the endpoint to be in IN NAK mode. The application can clear this interrupt by setting the CNAK bit in USBFS\_DIEPCTLx to 1.

#### Application Programming Sequence:

1. To stop sending any data on a specific IN endpoint, the application must set the IN NAK bit to 1. To set this bit to 1, the following fields must be programmed.
  - SNAK=1 in USBFS\_DIEPCTLx
2. Wait for the INEPNE interrupt in USBFS\_DIEPINTx to trigger. This interrupt indicates the module has stopped transmitting data on the endpoint.
3. The module can send active IN data on the endpoint when the application sets the NAK bit to 1 but the "NAK Active" interrupt has not yet been triggered.
4. The application can temporarily mask this interrupt by writing to the INEPNEM bit in DIEPMSK.
  - In DIEPMSK, INEPNEM=0
5. To exit endpoint NAK mode, the application must clear the NAK status bit (NAKSTS) in USBFS\_DIEPCTLx. This operation also clears the INEPNE interrupt (in USBFS\_DIEPINTx).
  - In USBFS\_DIEPCTLx, CNAK=1
6. If the application has masked this interrupt, it must be unmasked as follows:
  - In DIEPMSK, INEPNEM=1

### Disable IN Endpoint

Use the following sequence to disable a previously enabled specific IN endpoint.

#### Application Programming Sequence:

1. The application must first stop writing data on the AHB before disabling the IN endpoint.
2. The application must set the endpoint to NAK mode.
  - SNAK=1 in USBFS\_DIEPCTLx
3. Wait for the INEPNE interrupt in USBFS\_DIEPINTx.
4. The following bits in the USBFS\_DIEPCTLx register of the endpoint that must be disabled must be set to 1.
  - EPDIS=1 in USBFS\_DIEPCTLx
  - SNAK=1 in USBFS\_DIEPCTLx
5. The EPDISD interrupt in USBFS\_DIEPINTx indicates that the block has completely disabled the specified endpoint. At the same time the interrupt is triggered, the module also clears the following bits:
  - In USBFS\_DIEPCTLx, EPENA=0
  - In USBFS\_DIEPCTLx, EPDIS=0
6. The application must read the USBFS\_DIEPTSIZx register for periodic IN EP to calculate the amount of data transmitted on the endpoint via USB.
7. The application must clear the data in the endpoint transmit FIFO by setting the following fields in the USBFS\_GRSTCTL register to 1:
  - TXFNUM (in USBFS\_GRSTCTL)=Transmit FIFO number of the endpoint
  - TXFFLSH (in USBFS\_GRSTCTL)=1

The application must poll the USBFS\_GRSTCTL register until the module clears the TXFFLSH bit, indicating the FIFO flush operation has ended. To send new data on this endpoint, the application can re-enable the endpoint later.

### Universal Non periodic IN Data Transmission

#### Application Requirements:

1. Before establishing an IN transmission, the application must ensure that each data packet comprising an IN transmission, can fit into a single buffer.
2. For IN transmission,s, the transmission size field in the endpoint transmission size register indicates the active data amount of the current transmission, which consists of multiple maximum packet sizes and a single short packet. The short data packet is sent at the end of transmission.
  - To send multiple packets of the maximum packet size and append a short packet at the end of transmission.  
 Transmission size [EPNUM]=x×MPSIZ[EPNUM] + sp  
 If (sp > 0), packet count[EPNUM]=x + 1.  
 Otherwise, packet count [EPNUM]=x
  - To send a single zero length data packet:  
 Transmission size[EPNUM]=0  
 Packet count[EPNUM]=1
  - To send multiple packets of the maximum packet size and append a zero length packet at the end of transmission, the application must split the transfer into two parts.  
 The first part transmits a packet with the maximum packet size, while the second part transmits only a zero length packet.  
 First transfer: transmission size[EPNUM]=x×MPSIZ[epnum]; Packet count=n;  
 Second transfer: transmission size[EPNUM]=0; Packet count=1;

3. After enabling an endpoint for data transmission, the module updates the transmission size register. At the IN transmission end, the application must read the transmission size register to determine how much data in the transmit FIFO has been sent out via USB.
4. The amount of data written to the transmit FIFO=Initial transmission size programmed by the application-Final transmission size after module update.
  - Amount of data sent via USB=(Initial packet count programmed by application-Final packet count after module update) ×MPSIZ[EPNUM]
  - Remaining data to be sent via USB=(Initial transmission size programmed by application-Data already sent via USB)

#### Internal Data Flow:

1. The application must set the transmission size and packet count fields in the specific endpoint's register, and enable the endpoint to transmit data.
2. The application must also write the required data to the transmit FIFO of this endpoint.
3. Each time the application writes a data packet to the transmit FIFO, the transmission size of this endpoint is automatically decremented by the size of the data packet. The application continuously fetches data from memory to write into the transmit FIFO until the transmission size of this endpoint becomes 0. After writing data to the FIFO, the "packet count in FIFO" counter increments (this is a 3-bit counter maintained internally by the module, with one counter per IN endpoint transmit FIFO. In the IN endpoint FIFO, the maximum number of data packets maintained by the module is always eight.) For zero length packets, each FIFO has an additional dedicated flag indicating no data is present in the FIFO.
4. When data is written to the transmit FIFO, the module will send out this data upon receiving an IN token. For each packet sent out and receiving an ACK handshake signal in response, the packet count of this endpoint will decrement by 1 until the packet count reaches 0. Upon timeout, the packet count does not decrement.
5. For zero length packets (indicated by the internal zero length flag), the module issues a zero length packet in response to the IN token and decrements the packet count field value.
6. If an IN token is received for an endpoint whose corresponding FIFO has no data and its packet count field is zero, the module will generate an "IN token received when TxFIFO is empty" (ITTXFE) interrupt for that endpoint (provided the NAK bit of the endpoint is not set to 1). The module returns a NAK handshake signal on this asynchronous endpoint.
7. The module internally resets the FIFO pointer to the beginning and does not generate a timeout interrupt.
8. When the transmission size is 0 and the packet count is 0, the transmission complete (XFRC) interrupt for this endpoint will be generated, and the endpoint enable will be cleared.

#### Application Programming Sequence:

1. Program the USBFS\_DIEPTSIZx register using the transmission size and corresponding packet count.
2. Program the USBFS\_DIEPCTLx register using endpoint features, and set the CNAK and EPENA (Endpoint enable) bits to 1.
3. When sending a non-zero length data packet, the application must poll the USBFS\_DTXFSTSx register (where x is the FIFO number associated with the endpoint) to determine whether there is sufficient space in the data FIFO. Before writing data, the application can also use the TXFE bit (in USBFS\_DIEPINTx).

#### Universal Periodic IN Data Transmission

This section describes typical periodic IN data transmission

**Application Requirements:**

1. The application requirements 1, 2, 3, and 4 for universal non-periodic IN data transmission also apply to periodic IN data transmission (with slight modification to requirement 2).
  - The application can only send a number of data packets with the maximum packet size or several packets with the maximum packet size, plus a short packet at the end of transmission.  
To send multiple packets of the maximum packet size followed by a short packet at the end of transmission, the following condition must be met:  
Transmission size [EPNUM] =  $x \times \text{MPSIZ}[\text{EPNUM}] + \text{sp}$   
(Where  $x$  is an integer greater than 0, and the range of  $\text{sp}$  is  $0 - \text{MPSIZ}[\text{EPNUM}] - 1$ )  
If ( $\text{sp} > 0$ ), packet count [EPNUM] =  $x + 1$   
Otherwise, packet count [EPNUM] =  $x$ ;  
MCNT [EPNUM] = packet count [EPNUM]
  - The application cannot send a zero length packet at the end of transmission. The application can independently send a zero length data packet.
  - To send a single zero length data packet:  
Transmission size [EPNUM] = 0  
Packet count [EPNUM] = 1  
MCNT [EPNUM] = packet count [EPNUM]
2. The application can only schedule one frame of data transmission at a time.
  - $(\text{MCNT} - 1) \times \text{MPSIZ} \leq \text{XFERSIZ} \leq \text{MCNT} \times \text{MPSIZ}$
  - $\text{PKTCNT} = \text{MCNT}$  (in USBFS\_DIEPTSIZE $_x$ )
  - If  $\text{XFERSIZ} < \text{MCNT} \times \text{MPSIZ}$ , the last transmitted packet will be a short packet.
  - Note: MCNT is in USBFS\_DIEPTSIZE $_x$ , MPSIZ is in USBFS\_DIEPCTL $_x$ , PKTCNT is in USBFS\_DIEPTSIZE $_x$ , XFERSIZ is in USBFS\_DIEPTSIZE $_x$ .
3. Before receiving the IN token, the application must write the complete data to be sent in the frame into the transmit FIFO. Upon receiving an IN token, the module will perform the operation for an empty transmit FIFO even if only 1 double word of data remains to be written for the frame to be transmitted. When the transmit FIFO is empty:
  - The synchronous endpoint will respond with a zero length data packet.
  - The interrupt endpoint will respond with a NAK handshake signal.

**Internal Data Flow:**

1. The application must set the transmission size and packet count fields in the specific endpoint's register, and enable the endpoint to transmit data.
2. The application must also write the required data to the transmit FIFO associated with this endpoint.
3. Each time the application writes a data packet to the transmit FIFO, the transmission size of this endpoint is automatically decremented by the size of the data packet. The application continuously fetches data from memory to write into the transmit FIFO until the transmission size of this endpoint becomes 0.
4. When the periodic endpoint receives an IN token, the module will start transmitting data from the FIFO (if data exists in the FIFO). If there is no complete data packet in the FIFO for the frame to be transmitted, the module will generate an "IN token received when TxFIFO is empty" interrupt for this endpoint.
  - The synchronous endpoint will respond with a zero length data packet.
  - The interrupt endpoint will respond with a NAK handshake signal.

5. The packet count for an endpoint is decremented by 1 when:
  - For synchronous endpoints, when transmitting a zero length or non-zero length data packet
  - For interrupt endpoints, decrement when sending the ACK handshake signal.
  - When both the transmission size and packet count are 0, a transmission completed interrupt will be generated for this endpoint, and the endpoint enable bit will be cleared.
6. Within the "Periodic Frame Interval" (controlled by the PFIVL bit in USBFS\_DCFG), the module generates an IISOIXFR interrupt in USBFS\_GINTSTS whenever it detects that data in any synchronous IN endpoint FIFO—which should be empty in the current frame—has not been fully transmitted.

#### Application Programming Sequence:

1. Program the USBFS\_DIEPCTLx register using endpoint features, and set the CNAK and EPENA bits to 1.
2. Write the data to be transmitted in the next frame into the transmit FIFO.
3. Hardware triggers the ITTXFE interrupt (in USBFS\_DIEPINTx) indicating the application has not written all required data to the transmit FIFO.
4. If the interrupt endpoint is already enabled before detecting the interrupt, the interrupt will be ignored. If the interrupt endpoint is not enabled, enable this endpoint so that data can be sent upon receiving the next IN token.
5. When the hardware triggers the XFRC interrupt (in USBFS\_DIEPINTx) and no ITTXFE interrupt is generated in USBFS\_DIEPINTx, it indicates the success of a synchronized IN transmission,. When reading the USBFS\_DIEPTSIZx register, if the transmission size=0 and packet count=0 are always obtained, it indicates all data has been transmitted via USB.
6. Setting the XFRC interrupt (in USBFS\_DIEPINTx) indicates the successful completion of an interrupt IN transmission, regardless of whether the ITTXFE interrupt (in USBFS\_DIEPINTx) is generated. When reading the USBFS\_DIEPTSIZx register, if the transmission size=0 and packet count=0 are always obtained, it indicates all data has been transmitted via USB.
7. In the USBFS\_GINTSTS register, if the incomplete synchronous IN transmission (IISOIXFR) interrupt is set without any of the aforementioned interrupts being generated, it indicates that the module did not receive at least one periodic IN token in the current frame.

#### Incomplete Synchronization IN Data Transmission

This section describes the operations that the application must perform for incomplete synchronous IN data transmission

##### Internal Data Flow:

1. The synchronization IN transmission is considered incomplete when any of the following conditions are met:
  - The module received a corrupted sync IN token on at least one sync IN endpoint. At this point, the application detects an incomplete synchronous IN transmission interrupt (IISOIXFR bit in USBFS\_GINTSTS).
  - The application writes data to the transmit FIFO too slowly, and receives an IN token before completing the full data write to the FIFO. At this point, the application detects the "IN token received when TxFIFO is empty" interrupt in USBFS\_DIEPINTx. The application can ignore this interrupt, as it will eventually generate an incomplete synchronous IN transmission interrupt (IISOIXFR bit in USBFS\_GINTSTS) at the end of the periodic frame. The module will respond to the received IN token by sending a zero length data packet via USB.
2. The application must stop writing data to the transmit FIFO as soon as possible.

3. The application must set the NAK bit and disable bit of the endpoint.
4. The module will disable this endpoint, clear the disable bit, and trigger the "Endpoint Disable" interrupt.

#### Application Programming Sequence:

1. The application can ignore the "IN token received when TxFIFO is empty" interrupt in USBFS\_DIEPINTx for any isochronous IN endpoint, as this will ultimately generate an incomplete synchronous IN transmission interrupt (in USBFS\_GINTSTS).
2. Hardware-triggered incomplete synchronous IN transmission interrupt (in USBFS\_GINTSTS) indicates there is at least one incomplete synchronous IN transmission, on a synchronous IN endpoint.
3. The application must read the "Endpoint Control" register of all synchronized IN endpoints to detect endpoints with incomplete IN data transmission
4. The application must stop writing data to the "Periodic Transmit FIFO" associated with these endpoints.
5. Program the following fields in the USBFS\_DIEPCTLx register to disable the endpoint:
  - SNAK=1 in USBFS\_DIEPCTLx
  - EPDIS=1 in USBFS\_DIEPCTLx
6. Hardware triggers the "Endpoint Disable" interrupt in USBFS\_DIEPINTx, indicating the module has disabled this endpoint.
  - At this point, the application must either empty the data in the associated transmit FIFO or overwrite the existing data in the FIFO by enabling a new transmission endpoint in the next frame. To refresh the data, the application must use the USBFS\_GRSTCTL register.

### Stop Asynchronous IN Endpoint

This section describes how the application can stop an asynchronous endpoint.

#### Application Programming Sequence:

1. Disable the IN endpoint to be stopped. Set the STALL bit to 1 simultaneously.
2. EPDIS=1 in USBFS\_DIEPCTLx (when the endpoint is enabled)
  - STALL=1 in USBFS\_DIEPCTLx
  - The priority of the STALL bit is always higher than that of the NAK bit.
3. A hardware-triggered "Endpoint Disable" interrupt (in USBFS\_DIEPINTx) notifies the application that the module has disabled the specified endpoint.
4. The application must empty the non-periodic or periodic transmit FIFO based on the endpoint type. For non-periodic endpoints, the application must re-enable another non-periodic endpoint without stopping to transmit data.
5. When the application is ready to end the STALL handshake signal for this endpoint, it must clear the STALL bit in USBFS\_DIEPCTLx.
6. If the application sets or clears the STALL state of an endpoint upon receiving a SetFeature.Endpoint Halt or ClearFeature.Endpoint Halt command from the host, the STALL bit must be set to 1 or cleared before the status phase transfer of the control endpoint.

#### Special Case: Stop Controlling the OUT Endpoint

During the data phase of a control transmission, if the number of IN/OUT tokens sent by the host exceeds the value specified in the SETUP packet, the module must respond with STALL to these excess IN/OUT tokens. In this scenario, the application must enable the ITTXFE interrupt of USBFS\_DIEPINTx and the OTEPDIS interrupt of USBFS\_DOEPINTx during the data phase of the control transmission (when the module has completed transmitting the data amount specified by the SETUP packet). Subsequently,

when the application receives this interrupt, it must set the STALL bit in the corresponding endpoint control register to 1 and clear this interrupt.

## 35.6 Register Description

The application controls the USBFS module by performing read and write operations on the control and status registers through the AHB slave interface. All registers in the USBFS module are 32-bit registers with 32-bit aligned addresses, and can only be accessed in 32-bit mode.

Control and status registers are categorized as follows:

- USBFS System Control Register
- Module Global Register
- Host Mode Register
- Device Mode Register
- Power and Clock Gating Control Registers
- Data FIFO(DFIFO) Access Register

The USBFS system control register has a different base address from other registers. This register is independent of the USBFS module and controls the relevant settings of the USBFS module.

Only the module global register, power and clock gating control registers, and data FIFO access registers can be accessed in both host and device modes. When the USBFS module operates in one mode (host or device), the application must not access registers in the alternate role mode, such as accessing device mode registers while in host mode. If an illegal access occurs, a mode mismatch interrupt will be generated and reflected in the module interrupt register USBFS.GINTSTS.NMIS bit. When the module switches from one role mode to another, the registers in the new operating mode must be reprogrammed to the power on reset state.

### Control Status Register Memory Mapping

The host and device mode registers occupy different addresses. All registers are implemented within the AHB clock domain.

### 35.6.3 USBFS Global Register

These registers are available in both host mode and device mode, and do not require reprogramming when switching between these two modes.

#### 35.6.3.1 VBUS Control Register (USBFS\_GVBUSCFG)

This register can be used to set the VBUS value to ignore the state of the VBUS pin.

### 35.6.3.2 AHB Control Register (USBFS\_GAHBCFG)

This register can be used to configure the module after power-on or when changing role modes, mainly containing AHB system-related configuration parameters.

The application must program this register before starting any AHB or USB transactions. Do not change this register after initial programming.

### 35.6.3.3 USB Configuration Register (USBFS\_GUSBCFG)

This register can be used to configure the module after power on or when changing role modes. It contains configuration parameters related to USB and USB-PHY.

The application must program this register before starting any AHB or USB transactions. Do not change this register after initial programming.

| 2:0   | TOCAL           | FS timeout calibration               | <p>The additional latency introduced by the PHY includes the number of PHY clocks set by the application in this field, as well as the module's full-speed inter-packet timeout interval. The impact of delays introduced by different PHYs on the data line state varies. The standard USB timeout value for full-speed operation ranges from 16 to 18 bit times (inclusive). The application must program this field according to the enumeration speed. The number of bit times added per PHY clock is 0.25 bit times.</p> <div>  <b>Note</b><br/>           Active in both device and host modes.         </div> | RW     |

### 35.6.3.4 Reset Register (USBFS\_GRSTCTL)

The application resets various hardware features in the module through this register.

| 0   | CSRST | Core soft reset | <p>Reset the HCLK and PCLK domains as follows:<br/>Clear individual interrupt and all CSR register bits except:</p> <ul style="list-style-type: none"> <li>● GATEHCLK bit in USBFS_GCCTL</li> <li>● STPPCLK bit in USBFS_GCCTL</li> <li>● FSLSPCS bit in USBFS_HCFG</li> <li>● DSPD bit in USBFS_DCFG</li> </ul> <p>Reset all module state machines (excluding AHB slaves) to idle state and flush all transmit FIFOs and receive FIFOs.</p> <p>At the end of the last data phase in an AHB transmission, terminate all transactions on the AHB master as soon as possible. Terminate all USB transactions immediately.</p> <p>The application can perform a write operation to this bit at any time when a reset of the module is required. This bit is self-clearing. The block will clear this bit after all necessary logic is reset, which requires several clock periods depending on the current state of the module. Once this bit is cleared, software must wait for at least 3 PHY clock periods before accessing the PHY domain (synchronization delay). Additionally, the software must wait until bit 31 in this register is set to 1 (indicating the AHB master is idle) before it can start operation.</p> <p>Software reset is typically used in two scenarios: first, during software development, and second, after the user dynamically modifies the PHY selection bit in the aforementioned USB configuration register. When the user modifies the PHY, the corresponding clock will be selected for the PHY and used in the PHY domain. Once a new clock is selected, the PHY domain must be reset to ensure normal operation.</p> <div>  <b>Note</b><br/>           Active in both device and host modes.         </div> | RW     |

### 35.6.3.5 Global Interrupt Status Register (USBFS\_GINTSTS)

This register is used to interrupt the application via system-level events in the current mode (Device Mode or Host Mode). This register indicates the current mode.

The FIFO status interrupt is read-only; if software performs read and write operations on the FIFO while processing these interrupts, the FIFO interrupt flag will be automatically cleared.

Before enabling the interrupt bit, the application must clear the USBFS\_GINTSTS register during initialization to avoid generating any interrupts prior to initialization.

| 22  | DATAFSUSP | Data fetch suspended | <p>This interrupt is only active in DMA mode. This interrupt indicates that the module has stopped fetching data for the IN endpoint due to unavailable TxFIFO space or request queue space. The application uses this interrupt in the endpoint mismatch algorithm. For example, after detecting an endpoint mismatch, the application will perform the following operations:</p> <ul style="list-style-type: none"> <li>● Set the global non-periodic IN NAK handshake signal to 1</li> <li>● Disable IN endpoint</li> <li>● Clear FIFO</li> <li>● Determine the token sequence based on the IN token sequence learning queue</li> <li>● Re-enable endpoint</li> <li>● Clear global non-periodic IN NAK handshake signal</li> </ul> <p>If the global non-periodic IN NAK has been cleared but the module has not yet retrieved data from the IN endpoint, and an IN token is received simultaneously, the module will generate an "IN token received while FIFO is empty" interrupt. Then USBFS sends a NAK response to the host. To avoid the above situation, the application can check the DATAFSUSP interrupt in USBFS_GINTSTS, which ensures the global NAK handshake signal is cleared only after the FIFO is full. Additionally, the application can mask the "Interrupt upon receiving IN token when FIFO is empty" while clearing the global IN NAK handshake signal.</p> <p>Writing 1 to this bit clears it via software.</p> <div>  <b>Note</b><br/>           Active only in device mode.         </div> | RW     |

### 35.6.3.6 Global Interrupt Mask Register (USBFS\_GINTMSK)

This register is used in conjunction with the global interrupt status register (USBFS\_GINTSTS) to interrupt the application. If an interrupt bit is masked, the corresponding interrupt will not be generated, but the associated register bit will still be set to 1.

| Offset | Bit Position |         |        |          |         |        |      |        |          |            |                       |          |       |       |          |       |          |          |         |          |        |          |           |           |         |        |      |          |       |          |   |   |

### 35.6.3.7 Receive Status Debug Read/Status Read and Pop Register (USBFS\_GRXSTSR/USBFS\_GRXSTSP)

Reading the receive status debug read register returns the content at the top of the receive FIFO.

Reading the receive status read and pop register can additionally pop the data entry at the top of the RxFIFO. The interpretation of the receive status content differs between host mode and device mode.

When the receive FIFO is empty, the module ignores read or pop operations on this register and return the value 0x0000 0000. When the receive FIFO non-empty bit (RXFNE bit in USBFS\_GINTSTS) of the module interrupt register is set, the application must only pop the receive status FIFO.

The read offset: 0x1C

The pop offset: 0x20

#### Host Mode

### 35.6.3.10 Non periodic Transmit FIFO/Queue Status Register (USBFS\_HNPTXSTS)

This read-only register contains free space information for the non-periodic TxFIFO and non-periodic transmit request queue.

This register is enable only in host mode; inactive in device mode.

| 15:0  | INEPTXSA | IN endpoint TxFIFOx RAM start address        | This field contains the starting address of the memory of the IN endpoint send FIFOx. The address must be aligned with the 32-bit memory location. | RW     |

### 35.6.4 USBFS Host Mode Register

The host mode register affects the module operation in host mode. In device mode, accessing the host mode register is prohibited as it yields undefined results.

#### 35.6.4.1 Host Configuration Register (USBFS\_HCFG)

This register configures the module after power-on. Do not modify this register after initializing the host.

| 15:0  | FRIVL    | Frame interval | <p>The value programmed by the application in this field specifies the time interval between two consecutive SOF (FS) or Keep-Alive tokens (LS). This field contains the number of PHY clocks that constitute the desired frame interval. The application can only write values to this register after setting the port enable bit (PENA bit in USBFS_HPRT) of the host port control and status register to 1. If no value is programmed, the module calculates based on the PHY clock specified in the FS/LS PHY clock selection field (FSLSPCS in USBFS_HCFG) of the host configuration register. Do not change the value of this field after initial configuration. Set value=frame interval (ms) × (PHY clock frequency) - 1.</p> <div>  <b>Notice</b><br/>           When the application needs to change the frame interval time, it can modify the FRIVL bit.         </div> | RW     |

### 35.6.4.5 Host All Channels Interrupt Register (USBFS\_HAINT)

When an event occurs on the channel, the host all-channel interrupt register interrupts the application using the host channel interrupt bit in the module interrupt register (the HCINT bit in USBFS\_GINTSTS). Each channel corresponds to one interrupt bit, with a maximum of 16 bits.

When the application clears the interrupt through the corresponding host channel x interrupt register, the bit in this register is also cleared.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |       |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

### 35.6.4.7 Host Port Control and Status Register (USBFS\_HPRT)

This register is only available in host mode. Currently, the USBFS host supports only one port.

This register contains USB port-related information, such as USB reset, enable, suspend, resume, and connection status. The PENCHNG/PCDET bit in this register can trigger an application interrupt through the host port interrupt bit (HPRTINT bit in USBFS\_GINTST) in the module interrupt register. When a port interrupt occurs, the application must read this register and clear the bits that triggered the interrupt. The application must write 1 to this bit to clear the interrupt.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |      |          |    |    |    |    |      |       |    |          |      |       |    |      |          |   |         |      |       |       |

### 35.6.4.9 Host Channel x Interrupt Register (USBFS\_HCINTx) (x=0-15)

This register indicates the state of the channel when USB and AHB-related events occur. When the host channel interrupt bit (HCINT bit in USBFS\_GINTSTS) in the module interrupt register is set to 1, the application must read this register. Before performing a read operation on the register, the application must first read the host all-channel interrupt (USBFS\_HAINT) register to obtain the accurate channel number for the host channel x interrupt register. The application must clear the corresponding bits in this register to clear the corresponding bits in the USBFS\_HAINT and USBFS\_GINTSTS registers.

|------|---------|-------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 31:0 | DMAADDR | DMA address | This field stores the address of the memory used for DMA transfers when the host obtains data from the device endpoint or sends data to the device endpoint. This register increments at the end of each AHB transfer. | RW     |

### 35.6.5 USBFS Device Mode Register

The device mode register affects the module operation in device mode. In host mode, accessing the device mode register is prohibited as it yields undefined results.

#### 35.6.5.1 Device Configuration Register (USBFS\_DCFG)

This register configures the module into device mode after power-on, execution of certain control commands, or enumeration. Do not change this register after initial programming.

The module remains disconnected until the application clears this bit.</p> <ul style="list-style-type: none"> <li>● 0b0: Normal operation. This bit is cleared after a soft disconnect, causing the host to receive a device connected event. After reconnecting the device, the USB host will restart device enumeration.</li> <li>● 0b1: Enable the host to receive the device disconnection event.</li> </ul> <p>At full speed, the minimum duration for soft disconnect is specified as follows:</p> <ul style="list-style-type: none"> <li>● Suspended state: the minimum time is 1ms+2.5μs</li> <li>● Idle state: 2.5μs</li> <li>● Non-idle or suspend status: 2.5μs</li> </ul> | RW     |
| 0   | RWUSIG | Remote wake-up signaling | <p>When the application sets this bit to 1, the module initiates a remote wake-up signal to wake the USB host. The application must set this bit to 1 to make the module exit the suspend status. According to the USB 2.0 specification, the application must clear this bit within 1ms to 15ms after setting it to 1.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | RW     |

### 35.6.5.3 Device Status Register (USBFS\_DSTS)

This register indicates the status of the module when USB-related events occur. When an interrupt occurs, the endpoint information of the interrupt must be read from the device all-segment endpoint interrupt register (USBFS\_DAINTE).

### 35.6.5.6 Device All Endpoints Interrupt Register (USBFS\_DAINR)

When a active event occurs on an endpoint, the USBFS\_DAINR register interrupts the application via the device OUT endpoint interrupt bit or device IN endpoint interrupt bit (OEPINT or IEPINT bits in USBFS\_GINTSTS, respectively) in the USBFS\_GINTSTS register. Each endpoint corresponds to one interrupt bit, with a maximum of 16 interrupt bits for both OUT and IN endpoints. Bidirectional endpoints use the corresponding IN and OUT interrupt bits. When the application sets the bit to 1 and clears the bit in the corresponding device endpoint x interrupt register (USBFS\_DIEPINTx/USBFS\_DOEPINTx), the corresponding bit in this register is also set to 1 and cleared.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |        |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |  |  |  |  |  |  |

### 35.6.5.7 Device All Endpoints Interrupt Mask Register (USBFS\_DAINTRMSK)

The USBFS\_DAINTRMSK register is used in conjunction with the device endpoint interrupt register to interrupt the application when an event occurs on the device endpoint. However, the corresponding bit in the USBFS\_DAINTR register is still set to 1 for this interrupt.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |         |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |  |  |  |  |  |  |

|-------|----------|------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 31    | EPENA    | Endpoint enable  | The application sets this bit to 1 to initiate a data transfer on endpoint 0.<br>The module clears this bit before any of the following interrupts are triggered on this endpoint: <ul style="list-style-type: none"> <li>● SETUP phase done</li> <li>● Endpoint disable</li> <li>● Transmission completion</li> </ul>                                                                                                                              | RW     |
| 30    | EPDIS    | Endpoint disable | The application can set this bit to 1 even before the transfer on this endpoint is completed to stop data transmission on the endpoint. The application must wait until the endpoint disable interrupt occurs before considering the endpoint as disabled. The module clears this bit before the endpoint disable interrupt bit is set to 1. The application can set this bit to 1 only after the endpoint enable bit of this endpoint is set to 1. | RW     |
| 29:28 | Reserved | Reserved         | -                                                                                                                                                                                                                                                                                                                                                                                                                                                   | -      |
| 27    | STALL    | Set NAK          | Writing to this bit sets the NAK bit of the endpoint to 1.<br>Through this bit, the application can control the sending of NAK handshake on the endpoint. The module may also set this bit to 1 when the endpoint receives a SETUP packet.                                                                                                                                                                                                          | RW     |
| 26    | CNAK     | Clear NAK        | Writing to this bit clears the NAK bit of the endpoint.                                                                                                                                                                                                                                                                                                                                                                                             | RW     |
| 25:22 | TXFNUM   | TxFIFO number    | This value is set to the FIFO number allocated to IN endpoint 0. Only TX-FIFO0 can be used.                                                                                                                                                                                                                                                                                                                                                         | RW     |
| 21    | STALL    | STALL handshake  | The application can only set this bit to 1. When the endpoint receives a SETUP token, the module clears this bit. If the NAK bit, global IN NAK, or global OUT NAK and this bit are all set to 1, the STALL bit takes precedence.                                                                                                                                                                                                                   | RW     |

| 31  | EPENA          | Endpoint enable              | The application sets this bit to 1 to initiate a data transfer on endpoint. The module clears this bit before any of the following interrupts are triggered on this endpoint: <ul style="list-style-type: none"> <li>● Endpoint disabled</li> <li>● Transmission completion</li> </ul>                                                                                                                                                              | RW     |
| 30  | EPDIS          | Endpoint disable             | The application can set this bit to 1 even before the transfer on this endpoint is completed to stop data transmission on the endpoint. The application must wait until the endpoint disable interrupt occurs before considering the endpoint as disabled. The module clears this bit before the endpoint disable interrupt bit is set to 1. The application can set this bit to 1 only after the endpoint enable bit of this endpoint is set to 1. | RW     |
| 29  | SODDFRM        | Set odd frame                | Applies only to synchronous IN and OUT endpoints.<br>Writing to this field sets the even/odd frame (EONUM) field to odd frame.                                                                                                                                                                                                                                                                                                                      | RW     |
| 28  | SD0PID/SEVNFRM | Set DATA0 PID/Set even frame | <b>SD0PID:</b> Applicable only to interrupt/bulk IN endpoints. Writing to this field sets the endpoint data PID (DPID) field in this register to DATA0.<br><b>SEVNFRM:</b> Applicable only to synchronous IN endpoints. Writing to this field sets the even/odd frame (EONUM) field to even frame.                                                                                                                                                  | RW     |
| 27  | SNAK           | Set NAK                      | Writing to this bit sets the NAK bit of the endpoint to 1.<br>Through this bit, the application can control the sending of NAK handshake on the endpoint. The module can also set this bit of the IN endpoint to 1 when a transmission completed interrupt occurs or after a SETUP is received on the endpoint.                                                                                                                                     | RW     |

### 35.6.5.11 Device IN Endpoint x Interrupt Register (USBFS\_DIEPINTx) (x=0-15)

This register indicates the status of the endpoint when USB and AHB related events occur. When the IN endpoint interrupt bit (IEPINT bit in USBFS\_GINTSTS) in the module interrupt register is set to 1, the application must read this register. Before the application can read this register, it must first read the device all endpoints interrupt (USBFS\_DAINTE) register to obtain the correct endpoint number of the device endpoint x interrupt register. The application must clear the corresponding bit in this register in order to clear the corresponding bits in the USBFS\_DAINTE and USBFS\_GINTSTS registers.

### 35.6.5.12 Device IN Endpoint 0 Transfer Size Register (USBFS\_DIEPTSIZ0)

The application must modify this register before enabling endpoint 0. After enabling endpoint 0 by setting the endpoint enable bit (EPENA in USBFS\_DIEPCTL0) in the device control endpoint 0 control register, the module modifies this register. The application can only read this register after the module clears the endpoint enable bit.

Non-zero endpoints use registers for endpoints 1-15.

| 6:0   | XFRSIZ   | Transfer size | Indicates the amount of data included in one data transfer for endpoint 0, in bytes. The module only interrupts the application after these data have been transmitted. The transfer size can be set to the maximum packet size of the endpoint to interrupt at the end of each packet.<br>Each time a data packet from external memory is written to the TxFIFO, the module decrements this field. | RW     |

### 35.6.5.13 Device IN Endpoint x Transfer Size Register (USBFS\_DIEPTSIZx) (x=1-15)

The application must modify this register before enabling the endpoint. After the endpoint is enabled via the endpoint enable bit (EPENA bit in USBFS\_DIEPCTLx) in the USBFS\_DIEPCTLx register, the module modifies this register. The application can only read this register after the module clears the endpoint enable bit.

| 31    | Reserved | Reserved      | -                                                                                                                                                                                                                                                                                                                                                                                                                      | -      |
| 30:29 | MCNT     | Multi count   | For periodic IN endpoints, this field indicates the number of packets that must be sent per frame on the USB. The module uses this field to calculate the data PID for synchronous IN endpoints. <ul style="list-style-type: none"> <li>● 0b00: Setting prohibited</li> <li>● 0b01: 1 packet</li> <li>● 0b10: 2 packets</li> <li>● 0b11: 3 packets</li> </ul>                                                          | RW     |
| 28:19 | PKTCNT   | Packet count  | Indicates the number of data packets included in one data transfer on this endpoint. This field decrements each time a data packet (maximum size or short packet) is read from the TxFIFO.                                                                                                                                                                                                                             | RW     |
| 18:0  | XFRSIZ   | Transfer size | This field contains the amount of data included in one data transfer of the current endpoint, in bytes. The module only interrupts the application after these data have been transmitted. The transfer size can be set to the maximum packet size of the endpoint to interrupt at the end of each packet.<br>Each time a data packet from external memory is written to the TxFIFO, the module decrements this field. | RW     |

35.6.5.14 Device IN Endpoint x DMA Address Register (USBFS\_DIEPDMAx) (x=0-15)

This register is used to set the DMA address when the device endpoint is in DMA mode.

### 35.6.5.18 Device OUT Endpoint x Interrupt Register (USBFS\_DOEPINTx) (x=0-15)

This register indicates the status of the endpoint when USB and AHB related events occur. When the OUT endpoint interrupt bit (OEPINT bit in USBFS\_GINTSTS) in the USBFS\_GINTSTS register is set to 1, the application must read this register. Before the application can read this register, it must first read the USBFS\_DAINTE register to obtain the correct endpoint number of the USBFS\_DOEPINTx register. The application must clear the corresponding bit in this register in order to clear the corresponding bits in the USBFS\_DAINTE and USBFS\_GINTSTS registers.

### 35.6.5.19 Device OUT Endpoint 0 Transfer Size Register (USBFS\_DOEPTSIZ0)

The application must modify this register before enabling endpoint 0. After enabling endpoint 0 by setting the endpoint enable bit (EPENA in USBFS\_DIEPCTL0) in the device control endpoint 0 control register, the module modifies this register. The application can only read this register after the module clears the endpoint enable bit.

Non-zero endpoints use registers for endpoints 1-15.

| 6:0   | XFRSIZ   | Transfer size      | Indicates the amount of data included in one data transfer for endpoint 0, in bytes. The module only interrupts the application after these data have been transmitted. The transfer size can be set to the maximum packet size of the endpoint to interrupt at the end of each packet.<br>Each time a packet is read from the RxFIFO and written to external memory, the module decrements this field. | RW     |

### 35.6.5.20 Device OUT Endpoint x Transfer Size Register (USBFS\_DOEPTSIZE<sub>x</sub>) (x=1-15)

The application must modify this register before enabling the endpoint. After enabling the endpoint through the endpoint enable bit (EPENA bit in USBFS\_DOEPTCTL<sub>x</sub>) in the USBFS\_DOEPTCTL<sub>x</sub> register, the module modifies this register. The application can only read this register after the module clears the endpoint enable bit.

The application program clears this bit when USB communication resumes.                                                                           | RW     |

## 36 CAN FD Controller (CAN FD)

### 36.1 Introduction

CAN (Controller Area Network) bus is a bus standard that enables communication between microprocessors or devices without a host.

The CAN FD controllers (CAN1/CAN2) comply with the CAN bus protocol 2.0A and 2.0B and are upward compatible with CAN-FD.

The CAN bus controller can handle data transmission and reception on the bus. In this product, the CAN FD controller has 16 filter groups. Filters are used to select messages for the application to receive.

In the CAN FD controller, applications can send data to the bus through 1 high-priority Primary Transmit Buffer (PTB) and 3 Secondary Transmit Buffers (STB), with the transmission sequence determined by the transmit scheduler. Bus data is received through 8 Receive Buffers (RB). The 3 STBs and 8 RBs can be understood as a 3-stage FIFO and an 8-stage FIFO, both fully controlled by hardware.

CAN FD bus controllers can also support Time-trigger communication.

### 36.2 Features

- Fully supports CAN2.0A/CAN2.0B/CAN FD protocols
- CAN2.0 supports a maximum communication baud rate of 1Mbit/s
- Supports baud rate prescaler of 1 to 1/256 for flexible baud rate configuration
- 8 receive buffers
  - ▶ FIFO mode
  - ▶ Messages stored will not be overwritten by erroneous or unreceived data
- 1 high-priority PTB
- 3 STB
  - ▶ FIFO Mode
  - ▶ Priority arbitration method
- 16 independent filter groups
  - ▶ Support 11-bit standard ID and 29-bit extended ID
  - ▶ Programmable ID CODE bits and MASK bits
- Both PTB and STB support single send mode
- Supports silent mode
- Supports loopback mode
- Supports capturing transmission error types and locating bit arbitration lost bits
- Programmable error warning value
- Supports ISO11898-4 defined time-trigger CAN and receive timestamps

## 36.3 Functional Description

### 36.3.1 System Block Diagram

Figure 36-1 CAN FD System Block Diagram

### 36.3.2 Pin Description

Table 36-1 CAN Pin Description

| Pin name                | Direction | Description                                                                                            |
|-------------------------|-----------|--------------------------------------------------------------------------------------------------------|
| CANx_RX (x=1-2)         | Input     | CAN receive data signal                                                                                |
| CANx_TX (x=1-2)         | Output    | CAN sends data signal                                                                                  |
| CANx_TST_SAMPLE (x=1-2) | Output    | For observation only, sample bit set (communication clock width of one cycle after the sampling point) |
| CANx_TST_CLOCK (x=1-2)  | Output    | For observation only, baud rate (communication clock width of one cycle before the start of a bit)     |

### 36.3.3 Operating Mode

#### 36.3.3.1 Action Mode

Before using the CAN FD function, CAN FD function enable must be configured. Please refer to the description of the CAN global control register in the "Register Description" chapter.

The CAN FD controller has two operating modes: reset mode (CAN\_CFG\_STAT.RESET=1) and action mode (CAN\_CFG\_STAT.RESET=0). When initializing the module, first set the registers that can only be operated in reset mode (see the Register Description section for details) in reset mode, then exit reset mode and operate the remaining registers in action mode.

#### 36.3.3.2 Loopback Mode

CAN\_CTRL supports the following two loopback modes:

- Internal loopback

- External loopback

Both loopback modes can receive data frames sent by themselves, mainly used for testing purposes.

Internal loopback mode: Internally connects the receive data line to the transmit data line within the module, and transmit data is not output. In internal loopback mode, the node generates a self-acknowledge signal to avoid ACK errors.

External loopback mode maintains the connection with the transceiver, so the transmitted data can still appear on the CAN bus. With the help of the transceiver, CAN can receive its own transmitted data. In external loopback mode, the self-acknowledge signal can be generated or not by setting the SACK bit in the RCTRL register. When SACK=0, no self-acknowledge signal is generated; when SACK=1, a self-acknowledge signal is generated.

In external loopback mode with SACK=0, the following two situations may occur:

- Other nodes also receive the data frame sent by this node and send an ACK signal. In this case, the node can successfully send and receive data.
- If no other node returns an ACK signal, an ACK error will occur, causing the data to be retransmitted and the error counter to be incremented. In this case, it is recommended to use single send mode.

When returning from loopback mode to normal mode, in addition to clearing the mode bit, it is also necessary to perform a software reset of CAN\_CTRL.

Figure 36-2 CAN FD LBMI and LBME Schematic Diagram

### 36.3.3.3 Silent Mode

Silent mode can be used to monitor CAN network data. In silent mode, data can be received from the CAN bus, but no data is sent to the bus. Set TCMD.LOM to 1 to enter silent mode, and clear it to exit silent mode.

External loopback mode can be combined with silent mode to form external loopback silent mode. In this mode, CAN can be considered a silent receiver but can send data when necessary. In external loopback silent mode, frames containing self-acknowledge signals are allowed to be sent, but the node will not generate error flags or overload frames.

### 36.3.4 Baud Rate Setting

The CAN communication clock (can\_clk) is used to generate the baud rate, which can be selected from system clock division or an independent clock (see the "Working Clock Specifications" section in the "Clock Module Unit (CMU)" chapter). It is specified by the CMU\_CANCKCFGR register. The clock selection must meet the condition that PCLK0 (CAN control logic clock) is 1.5 times or more of the CAN communication clock.

The diagram below shows the CAN bit time definition. The upper part above the dashed line represents the bit time specified by the CAN protocol, and the lower part below the dashed line represents the bit time defined by the CAN-CTRL. Where, segment1 and segment2 can be set through the SBT and FBT registers. The SBT and FBT registers can only be set when CAN\_CFG\_STAT.RESET=1, i.e., during CAN software reset. SBT register is used for the arbitration segment of CAN2.0 and CAN FD, and the FBT register is used for the CAN FD data segment.

For FD communication, it is recommended to select a communication clock of 20MHz/40MHz/80MHz.

Figure 36-3 CAN Bit Time Definition Diagram

Please refer to the following formula for the TQ calculation method, where PRESC is set through the S\_PRESC bit in the SBT register or the F\_PRESC bit in the FBT register.  $f_{can\_clk}$  is the CAN communication clock frequency.

$$S\_TQ = \frac{S\_PRESC + 1}{f_{can\_clk}}$$

$$F\_TQ = \frac{F\_PRESC + 1}{f_{can\_clk}}$$

The bit timing calculation method should refer to the following formula, where S\_segment1 and S\_segment2 are configured through the S\_SEG\_1 bit and S\_SEG\_2 bit of the SBT register, and F\_segment1 and F\_segment2 are configured through the F\_SEG\_1 bit and F\_SEG\_2 bit of the FBT register.

$$Slow\_BT = t_{s\_segment1} + t_{s\_segment2} = ((S\_SEG\_1 + 2) + (S\_SEG\_2 + 1)) \times S\_TQ$$

$$Fast\_BT = t_{f\_segment1} + t_{f\_segment2} = ((F\_SEG\_1 + 2) + (F\_SEG\_2 + 1)) \times F\_TQ$$

Table 36-2 CAN Bit Time Setting Rules

| Bit         | Predetermined Area                                               | Rule                             |
|-------------|------------------------------------------------------------------|----------------------------------|
| SBT.S_SEG_1 | [0..63] CAN2.0 bits (slow)<br>[0..63] CAN FD nominal bits (slow) | SEG_1 ≥ SEG_2 + 1<br>SEG_2 ≥ SJW |
| SBT.S_SEG_2 | [0..7] CAN2.0 bits (slow)<br>[0..31] CAN FD nominal bits (slow)  |                                  |
| SBT.S_SJW   | [0..15] CAN2.0 bits (slow)<br>[0..15] CAN FD nominal bits (slow) |                                  |
| FBT.F_SEG_1 | [0..15] CAN FD data bits (fast)                                  | SEG_1 ≥ SEG_2<br>SEG_2 ≥ SJW     |
| FBT.F_SEG_2 | [0..7] CAN FD data bits (fast)                                   |                                  |
| FBT.F_SJW   | [0..7] CAN FD data bits (fast)                                   |                                  |

The following is a recommendation for CAN FD baud rate settings for reference only.

- PSP: Primary Sample Point
- SSP: Secondary Sample Point
- Seg 1: Segment 1
- Seg 2: Segment 2
- TDC: Transmitter Delay Compensation

Table 36-3 Baud Rate Setting Recommendations for 20MHz Communication Clock

| Bit Rate [Mbit/s]  | PSP [%] | SSP [%] | Prescaler | Bit Time [TQ] | Seg 1 [TQ] | Seg 2 [TQ] | SJW [TQ] | TDC [CAN Communication Clock] |

## 36.3.5 Transmission Processing

### 36.3.5.1 Transmit Buffer

CAN\_CTRL provides two transmit buffers for sending data: the Primary Transmit Buffer (PTB) and the Secondary Transmit Buffer (STB). PTB has the highest priority but can only buffer one frame of data. STB has a lower priority than PTB but can buffer 3 frames of data, and the 3 frames in STB can operate in FIFO mode or priority arbitration mode.

The 3 frames in STB can be set to send all at once by setting the TSALL bit in the TCMD register to 1. In FIFO mode, the data written first is sent first. In priority mode, data with a smaller ID is sent first.

Data in PTB has the highest priority, so PTB transmission can delay STB transmission, but STB that has won arbitration and started transmission cannot be delayed by PTB transmission.

PTB and STB can be accessed through the TBUF register. Select PTB or STB by setting the TBSEL bit in the TCMD register. TBSEL=0 selects PTB; TBSEL=1 selects STB. Select the next SLOT in STB by setting the TSNEXT bit in the TCTRL register. The correspondence is shown in the diagram below:

Set TSNEXT bit to mark a slot filled and to jump to the next message slot

Figure 36-4 CAN FD TBUF Register Write Transmit Buffer and Schematic Diagram

### 36.3.5.2 Data Transmission

Before starting transmission, ensure that the data to be sent in PTB or STB has been filled, and then start PTB or STB transmission. Data refilling is not allowed during transmission.

The steps for setting up data transmission are as follows:

- Step1.** Set TBSEL to select the transmit BUF from PTB and STB;
- Step2.** Write the data to be sent through the TBUF register;
- Step3.** If STB is selected, set TSNEXT=1 to complete the loading of all STB SLOTS;
- Step4.** Send enable;
  - Use TPE for PTB transmission.
  - Use TSALL or TSONE for STB transmission.
- Step5.** Send complete status acknowledgment:
  - Use TPIF for PTB transmission completion, and TPIE to enable TPIF;
  - Use TSIF for STB transmission completion when using TSONE, and TSIE to enable TSIF;
  - Use TSIF for STB transmission completion when using TSALL. In this case, TSIF is set after all STB SLOT data to be sent is sent, and TSIE is used to enable TSIF.

### 36.3.5.3 Single Data Transmission

When automatic retransmission is not required, single send mode can be set through registers. The CFG\_STAT.TPSS bit is used for single send mode setting for PTB, and the CFG\_STAT.TSSS bit is used for STB. When data is successfully sent, the actions in single send mode are the same as those in normal send mode. However, when data is not successfully sent, the following results occur:

- TPIF is set (TPIE=1), and the corresponding BUF SLOT data is cleared.
- When there is an error in transmission, KOER is updated, and BEIF is set (BEIE=1).
- In case of arbitration lost, ALIF is set (ALIE=1).

In single send mode, TPIF alone cannot be relied upon to determine transmission completion. It is necessary to use BEIF and ALIF together to determine whether transmission is complete.

### 36.3.5.4 Cancel Data Transmission

Data transmission that has been requested but not yet executed can be canceled through TPA or TSA. The following situations may occur when canceling data transmission:

- During arbitration:

- ▶ If the node loses arbitration, data transmission is canceled.
- ▶ If the node wins arbitration, data transmission continues.
- Data sending:
  - ▶ Data is successfully sent and ACK is received. The corresponding flags and statuses are set normally. Data transmission is not canceled;
  - ▶ Data is successfully sent but no ACK is received. Data transmission is canceled, and the error counter is incremented.
  - ▶ For data transmission set by TSALL=1, the STB SLOT data being sent is sent normally, and the STB SLOT that has not started sending is canceled.

The results of canceling data transmission are as follows:

- TPA releases PTB and sets TPE=0.
- TSA releases one STB SLOT or all STB SLOTS depending on whether TSONE or TSALL is enabled for transmission.

### 36.3.6 Reception Processing

#### 36.3.6.1 Receive Buffer

CAN\_CTRL provides 8 SLOT receive buffers for storing received data. These 8 SLOT receive buffers operate in FIFO mode. RB SLOT received data can be read through the RBUF register. The earliest received data is always read first, and the read RB SLOT is released by setting RREL=1 in the RCTRL register, pointing to the next RB SLOT.

The diagram below shows the schematic for reading RB SLOT through RBUF.

Figure 36-5 CAN RBUF Register Read Receive Buffer Schematic Diagram

#### 36.3.6.2 Receive Filter Register Set

CAN\_CTRL provides 16 groups of 32-bit filters for filtering received data to reduce CPU load. The filters can support standard format 11-bit ID or extended format 29-bit ID. Each filter group has a 32-bit ID CODE register and a 32-bit ID MASK register. The ID CODE register is used to compare the received CAN ID, and the ID MASK register is used to select the CAN ID bits for comparison. When the corresponding ID MASK bit is 1, the ID CODE of that bit is not compared.

Received data is received if it passes through any one of the 16 filter groups. The received data is stored in RB; otherwise, it is not received or stored.

Each filter group is enabled or disabled through the ACFEN register. ID CODE and ID MASK are set through the SELMASK bit in the ACFCTRL register. When SELMASK=0, it points to ID CODE; when SELMASK=1, it points to ID MASK. Filters are selected through the ACFADR bit in the ACFCTRL register. ID CODE and ID MASK are accessed through the ACF register and can only be set when CFG\_STAT.RESET=1, i.e., during CAN software reset. Refer to the diagram below for the method of accessing filter groups through the CAN ACF register.

Figure 36-6 CAN ACF Register Access Filter Group Schematic Diagram

### 36.3.6.3 Data Reception

The receive filter groups can filter out unwanted received data, reducing the occurrence of interrupts and RB reads, thereby reducing CPU load. The steps for setting up received data are as follows:

- Step1.** Set filter groups.
- Step2.** Set RFIE, RAFIE, and AFWL.
- Step3.** Wait for RFIF or RAFIF.
- Step4.** Read the earliest received data from the RB FIFO through RBUF.
- Step5.** Set RREL=1 to select the next RB SLOT.
- Step6.** Repeat steps 4 and 5 until it is confirmed that RB is empty through RSTAT.

### 36.3.7 Error Handling

CAN\_CTRL can not only automatically handle some errors, such as automatically retransmitting data or discarding received frames containing errors, but also report errors to the CPU through interrupts.

CAN nodes have the following 3 error states:

- Error Active: The node automatically sends an active error flag when an error is detected.
- Error Passive: The node automatically sends a passive error flag when an error is detected.
- Bus Off: In this state, the node no longer affects the entire CAN network.

CAN\_CTRL provides two counters, TECNT and RECNT, for counting errors. The TECNT and RECNT counters are incremented or decremented according to the rules specified in the CAN protocol. Additionally, a programmable CAN error warning LIMIT register is provided to generate error interrupts to notify the CPU.

There are the following five types of errors during CAN communication, which can be identified through the KOER bit in the EALCAP register.

- Bit error
- Wrong form
- Stuff Error
- Acknowledgment error
- CRC error

### 36.3.8 BUS OFF

When the number of transmission errors exceeds 255, the CAN node automatically enters Bus Off state and no longer participates in CAN communication until it returns to Error Active state. The Bus Off state of the CAN node can be confirmed by checking the CFG\_STAT.BUSOFF bit. An EIF interrupt is generated when BUSOFF is set.

There are the following two methods for CAN to recover from Bus Off state to Error Active state:

- Power-on reset
- Received 128 consecutive 11-bit stealth bit sequences (recovery sequence)

In Bus Off state, the TECNT value remains unchanged, and RECNT is used to count the recovery sequence. After recovery from Bus Off state, TECNT and RECNT are reset to 0.

### 36.3.9 Arbitration lost Position Capture

CAN\_CTRL can precisely capture the arbitration lost bit position and reflect it in the ALC register. The ALC register stores the bit position of the most recent arbitration lost bit. If the node wins arbitration, the ALC bit is not updated.

**The ALC Value Is Defined As Follows:**

After the SOF bit, the ALC for the first ID data bit is 0, the ALC for the second ID data bit is 1, and so on. Since arbitration only occurs in the arbitration field, the maximum value of ALC is 31. For example, in an arbitration between a standard format remote frame and an extended frame, if the extended frame fails at the IDE bit, then ALC=12.

### 36.3.10 Time-Triggered TTCAN

CAN\_CTRL provides partial (level 1) hardware support for the time-triggered communication method specified in ISO11898-4. This chapter introduces the TTCAN function from the following five sections.

#### 36.3.10.1 TBUF Behavior in TTCAN Mode

##### TTTBM=1

When TTTBM=1, PTB and STB SLOTS together form TB SLOT, and the transmit BUF is specified through the TBPTR register. TBPTR=0 points to PTB, TBPTR=1 points to STB SLOT1, and so on. The host can mark transmit BUF SLOTS through the TBE and TBF registers. At this time, the TBSEL and TSNEXT registers are meaningless and can be ignored.

When TTTBM=1, PTB does not have any special attributes and is the same as STB SLOT. The transmission completion flag also uses TSIF.

In TTCAN mode, the transmit BUF does not have FIFO mode or priority arbitration mode, and only one selected SLOT can transmit data.

In TTCAN mode, transmission start requires a time-triggered method. TPE, TSONE, TSALL, TPSS, and TPA are fixed to 0 and ignored.

##### TTTBM=0

When TTTBM=0, event-driven communication and receive timestamp functions are used in combination. In this mode, the functions of PTB and STB are the same as when TTEN=0. Therefore, PTB always has the highest priority, and STB can operate in FIFO mode or priority arbitration mode.

#### 36.3.10.2 TTCAN Function Description

After power-on, the Time Master needs to be initialized according to the ISO 11898-4 protocol. In a CAN network, there can be up to eight potential Time Masters. Each Time Master has its own reference message ID (last three bits of the ID). These potential Time Masters send their respective reference messages based on their priorities.

After TTEN=1, the 16-bit counter starts working. When a reference message is successfully received or the Time Master successfully sends a reference message, the CAN controller copies Sync\_Mark to Ref\_Mark, and Ref\_Mark sets the cycle time to 0. Successfully receiving a reference message sets the RIF

flag, and successfully sending a reference message sets the TPIF flag or TSIF flag. At this time, the host needs to prepare the trigger conditions for the next action.

The trigger condition can be a receive trigger. This trigger only triggers an interrupt and can be used to detect when an expected message has not been received.

The trigger condition can also be a transmit trigger. This trigger starts transmitting data in the TBUF SLOT specified by the TTPTR register. If the selected TBUF SLOT is marked as empty, transmission does not start, but the interrupt flag is set.

### 36.3.10.3 TTCAN Timing

CAN\_CTRL supports ISO 11898-4 level 1. It includes a 16-bit counter that operates under the bit time defined by S\_PRESC, S\_SEG\_1, S\_SEG\_2. If TTEN=1, there is an additional prescaler T\_PRESC.

At the SOF of a frame of data, the counter value is Sync\_Mark. If the frame is a reference message, Sync\_Mark is copied to Ref\_Mark. The cycle time is equal to the counter value minus Ref\_Mark. This time is used as a timestamp for received messages or a trigger time baseline for transmitted messages.

### 36.3.10.4 TTCAN Trigger Mode

The TTYPE register defines the TTCAN trigger method, the TTPTR register specifies the transmit SLOT, and TT\_TRIG specifies the cycle time of the trigger.

The following 5 trigger methods are included:

- Immediate Trigger
- Time Trigger
- Single Transmit Trigger
- Transmit Start Trigger
- Transmit Stop Trigger

Except for the immediate trigger method, all triggers use the TTIF flag. When TTTBM=1, only the time-triggered method is supported.

#### Immediate Trigger

The trigger is started by writing the high bit of TT\_TRIG (the value written does not matter). In this mode, the data in the TBUF SLOT selected by TTPTR is immediately sent. TTIF is not set.

#### Time Trigger

The time-triggered method only generates an interrupt by setting the TTIF flag and has no other functions. If a node expects to receive expected data within a specific time window, the time-triggered method can be used. If the TT\_TRIG value is less than the actual cycle time, TEIF is set with no other action.

#### Single Transmit Trigger

The single transmit trigger method is used to send data within an execution time window. At this time, the TSSS bit is ignored.

The maximum of 16 cycle time ticks specified by ISO11898-4 is set through the TEW bit, with a setting range of 1-16. If data is not started to be sent within the specified transmit enable time window, the frame is discarded. The corresponding transmit BUF SLOT is marked as empty, and AIF is set. The data in the corresponding transmit BUF is not overwritten because it can be retransmitted by setting TPF.

If the TT\_TRIG value is less than the actual cycle time, TEIF is set with no other action.

### Transmit Start Trigger

The transmit start trigger method is used for arbitration within a time window. TSSS is used to determine whether to use auto-retransmit or single send mode. If the message specified by the TTPTR register is not successfully sent, the transmit stop trigger can be used to stop the transmission.

If the TT\_TRIG value is less than the actual cycle time, TEIF is set with no other action.

### Transmit Stop Trigger

The transmit stop trigger method is used to stop a transmission that has already started through the transmit start trigger method. If the transmission is stopped, the transmit frame is discarded, AIF is set, and the selected TBUF SLOT is marked as empty. However, the data in the TBUF SLOT is not overwritten and can be retransmitted by setting TPF.

If the TT\_TRIG value is less than the actual cycle time, TEIF is set and the stop is executed.

#### 36.3.10.5 TTCAN Trigger Gate Time

The TTCAN trigger watchdog time function is similar to the watchdog function and is used when TTTBM=1. It is used to watchdog the time since the last successful reception of a reference message. The reference message can be received within the cycle time or after an event. The application should set an appropriate watchdog time based on specific circumstances.

If the cycle count equals TT\_WTRIG, WTIF is set. The watchdog trigger is turned off by writing 0 to WTIE.

If TT\_WTRIG is less than the actual cycle time, TEIF is set.

### 36.3.11 TDC and RDC

During CAN FD communication, data delay may exceed one bit time, so compensation is required. TDC (Transmitter Delay Compensation) and RDC (Receiver Delay Compensation) are used for data delay compensation. TDC requires software control, while RDC is automatically enabled without software control. TDC uses a secondary sample point (SSP) to compensate for data delay. As shown in the following figure:

Figure 36-7 TDC Functional Block Diagram

When TDC is enabled, the controller can automatically determine the transmitter delay, and the SSP Offset can be set by configuring the TDC.SSPOFF register. It is recommended to set the SSP Offset to the same value as the  $t_{F\_segment1}$  setting.

### 36.3.12 Upward Compatibility with CAN-FD Function

When CAN FD function is disabled, CAN-CTRL automatically ignores CAN FD frames even when received in a network that includes CAN FD, without returning an ACK. It will send or receive the next CAN 2.0B frame once the bus is idle.

### 36.3.13 RAM ECC Function

Each CAN module contains a RAM memory that is used as the transmit buffer (TBUF), receive buffer (RBUF), and receive filter (ACF) for the CAN module.

In CAN RAM, the transmit buffer (TBUF) starts at address 0x00000000. Each TBUF is 72 bytes in size, arranged in order from low to high addresses as PTB, STB1-STB3. The receive buffer (RBUF) starts at address 0x00000120. Each RBUF is 72 bytes in size, arranged in order from low to high addresses as RBUF1-RBUF8. The receive filter (ACF) starts at address 0x000003A8. Each ACF is 8 bytes in size, arranged in order from low to high addresses as ACF1-ACF16.

Table 36-6 CAN RAM Address Mapping

| CAN RAM Element | CAN RAM Address Range |
|-----------------|-----------------------|
| PTB             | 0x00000000-0x00000047 |
| STB             | 0x00000048-0x0000011F |
| RBUF            | 0x00000120-0x000003A7 |
| ACF             | 0x000003A8-0x00000427 |

RAM is equipped with ECC checking, which involves correcting 1-bit errors and checking for 2-bit errors. ECC checking has an error injection function. Based on the settings of CAN\_RAM\_EIEN register and CAN\_RAM\_EIBIT0/CAN\_RAM\_EIBIT1 registers, the hardware circuitry will invert the data read from RAM bit by bit to achieve error injection. By setting CAN\_RAM\_EIBIT0/CAN\_RAM\_EIBIT1 registers, 1-bit or multi-bit errors can be induced. Since ECC checking is a single error correction and double error detection code, errors exceeding 2-bit may not be detected. The CAN\_RAM\_ECCERRADDR register records the access address when a 1-bit or 2-bit ECC error occurs in CAN RAM (as shown in the table above).

### 36.3.14 Software Reset Function

Software reset function is achieved by setting the CFG\_STAT.RESET bit to 1. The reset scope of the software reset function is shown in the table below.

Table 36-7 Software Reset Range Table

| Register Bit Name | Software Reset | Remark                              | Register Bit Name | Software Reset | Remark                                                |
|-------------------|----------------|-------------------------------------|-------------------|----------------|-------------------------------------------------------|
| ACFADR            | No             | -                                   | F_SEG_1           | Yes            | Writable only during software reset                   |
| ACODE             | No             | Writable only during software reset | F_SEG_2           | Yes            | Writable only during software reset                   |
| AE_x              | No             | -                                   | F_SJW             | Yes            | Writable only during software reset                   |
| AFWL              | No             | -                                   | KOER              | Yes            | -                                                     |
| AIF               | Yes            | -                                   | LBME              | Yes            | -                                                     |
| ALC               | Yes            | -                                   | LBMI              | Yes            | -                                                     |
| ALIE              | No             | -                                   | RACTIVE           | Yes            | Immediately stops reception and does not generate ACK |
| ALIF              | Yes            | -                                   | RAFIE             | No             | -                                                     |

| Register Bit Name | Software Reset | Remark                              | Register Bit Name | Software Reset | Remark                                     |
|-------------------|----------------|-------------------------------------|-------------------|----------------|--------------------------------------------|
| AMASK             | No             | Writable only during software reset | RAFIF             | Yes            | -                                          |
| BEIE              | No             | -                                   | RBALL             | Yes            | -                                          |
| BEIF              | Yes            | -                                   | RBUF              | Yes            | RB is marked as empty, value indeterminate |
| BUSOFF            | No             | Cleared by writing 1                | RECNT             | No             | Cleared by writing 1 to BUSOFF             |

### 36.4.2 CAN Receive BUF Register (CAN\_RBUF)

Offset: 0x00-0x4F

Reset: 0xFFFFFFFF

The RBUF register points to the RB SLOT address of the earliest received CAN mailbox. The RBUF register can be read in any order.

The KOER bit is the EALCAP.KOER register, which is meaningful only when RBALL=1.

The TX bit indicates that a message sent by itself is received in loopback mode.

The CYCLE\_TIME bit is valid only in TTCAN mode and indicates the cycle time at the start of SOF.

CAN\_RBUF only supports WORD access.

The data format of the CAN receive mailbox is as follows:

Table 36-11 Standard Format CAN Receive Mailbox Format

| Address | Bit7             | Bit6 | Bit5 | Bit4 | Bit3     | Bit2     | Bit1 | Bit0 | Function |
|---------|------------------|------|------|------|----------|----------|------|------|----------|
| RBUF    | ID[7:0]          |      |      |      |          |          |      |      | ID       |
| RBUF+1  | Reserved         |      |      |      |          | ID[10:8] |      |      | ID       |
| RBUF+2  | Reserved         |      |      |      |          |          |      |      | ID       |
| RBUF+3  | Reserved         |      |      |      |          |          |      |      | ID       |
| RBUF+4  | IDE=0            | RTR  | FDF  | BRS  | DLC[3:0] |          |      |      | Control  |
| RBUF+5  | KOER[2:0]        |      |      | TX   | Reserved |          |      |      | Status   |

|                | TX                     | This bit is set to 1 when receiving a message sent by itself in loopback mode                                                                                                                                                                                                                                                                                                                                                                                                                                                       |               |                  |                  |        |               |     |               |   |        |               |     |        |    |        |    |        |    |        |    |        |    |        |    |        |    |

### 36.4.3 CAN Transmit BUF Register (CAN\_TBUF)

Offset: 0x50-0x97

Reset: 0xFFFFFFFF

The TBUF register points to the next empty CAN transmit BUF SLOT. The TBUF register can be read in any order. The corresponding TBUF SLOT is marked as written by writing 1 to TSNEXT, thereby pointing to the next TBUF SLOT.

CAN\_TBUF only supports WORD access.

The data format of the CAN sending mailbox is as follows:

Table 36-15 Standard Format CAN Transmit Mailbox Format

| Address | Bit7     | Bit6 | Bit5 | Bit4 | Bit3     | Bit2     | Bit1 | Bit0 | Function |
|---------|----------|------|------|------|----------|----------|------|------|----------|

## 36.5 Precautions

### 36.5.1 CAN Bus Anti-Interference Measures

The CAN bus is widely used in the automotive, industrial control, and other industries. If the electromagnetic environment of the CAN application site is harsh, with factors such as circuit imbalance, spatial electromagnetic fields, and power grid inlet lines, it can cause a large amount of communication noise on the CAN bus due to radiation and conduction interference. This leads to an increase in bus error frames, frequent retransmissions, and a failure for correct data to arrive in a timely manner, seriously affecting data communication quality. Therefore, in practical applications, efforts should be made to eliminate noise interference and ensure stable operation of the CAN bus network.

The following are several commonly used CAN bus anti-interference measures (including but not limited to):

- Add Electrical Isolation for the CAN Bus Interface
- Common transceiver signal ground
- Use shielded twisted pair cables and ground them properly
- Increase the twisting rate of CAN transmission lines
- Add signal protector
- Improve network topology
- Application layer software anti-jamming mechanism

### 36.5.2 CAN Controller Noise Constraints

In the CAN bus network, ensure that the communication bit time meets the requirements of the standard protocol. If noise interference that does not meet the bit time width is introduced, it may cause abnormal operation of the CAN controller.

## 37 Controller Area Network (MCAN)

### 37.1 Introduction

The Controller Area Network (CAN) subsystem consists of two CAN modules, a shared message RAM memory for the base addresses of these components, see the "Memory Mapping" chapter.

Both CAN modules (MCAN1 and MCAN2) comply with ISO 11898-1:2015 (CAN Protocol Specification Version 2.0 Parts A, B) and CAN FD Protocol Specification Version 1.0 (CAN with Flexible Data-Rate Specification Version 1.0).

The 4KB message RAM memory can realize the filter (Rx Filter), receive FIFO (Rx FIFO), receive buffer (Rx Buffer), transmit event FIFO (Tx Event FIFO), and transmit buffer (Tx Buffer) functions. The message RAM is shared between MCAN1 and MCAN2 modules.

### 37.2 Features

- Compliant with ISO 11898-1:2015 standard
- CAN FD supports up to 64 bytes of data per frame for transmission and reception
- Supports CAN error logging
- Supports AUTOSAR and SAE J1939
- Support the receive filtering function
- Two configurable receive FIFOs
- Dedicated signal output on reception of high-priority messages
- Up to 64 dedicated receive buffers
- Up to 32 dedicated transmit buffers
- Configurable transmit FIFO or queue
- Configurable transmit event FIFO
- Message RAM accessible directly by the host CPU
- MCAN1 and MCAN2 share a common message RAM
- Supports programmable loopback test mode
- Supports maskable module interrupts
- Two clock domains: CAN core clock and APB bus interface clock

## 37.3 Functional Description

### 37.3.1 MCAN System Block Diagram

Figure 37-1 MCAN System Block Diagram

#### CAN Core

The CAN core includes a protocol controller and transmit/receive shift registers. It supports all protocol functions defined in ISO 11898-1:2015 and allows for both 11-bit standard IDs and 29-bit extended IDs.

#### Synchronization

The synchronization module synchronizes the signal from the APB clock domain to the CAN core clock domain, and synchronizes the signal from the CAN core clock domain to the APB clock domain.

The APB clock domain provides the MCAN control logic clock, while the CAN core clock domain provides the MCAN communication clock. For details, refer to the "Working Clock Specifications" section in the "Clock Module Unit (CMU)" chapter. To ensure stable MCAN communication, the control logic clock frequency must be greater than or equal to the communication clock frequency.

## Transmit Processing Unit

This unit controls the transfer of messages from the external message RAM to the CAN core. Up to 32 transmit buffers can be configured for message transmission. Transmit buffers can be used as dedicated transmit buffers, a transmit FIFO (or queue), or a combination of both. A Transmit Event FIFO stores the transmission timestamp along with the corresponding message ID. Transmission cancellation is also supported.

## Receive Processing Unit

This unit controls the transfer of received messages from the CAN core to the external message RAM. It supports two configurable receive FIFOs and up to 64 dedicated receive buffers for storing messages that pass the receive filters. Unlike receive FIFOs, dedicated receive buffers are only used to store messages with specific IDs. Each received message is stored together with its receive timestamp. Up to 128 filters can be defined for 11-bit standard IDs, and up to 64 filters for 29-bit extended IDs.

## APB Interface

Connects the MCAN to the APB bus.

## Message RAM

The interface connects MCAN access to an external 4KB message RAM through a RAM controller and arbiter.

## Dual Interrupt Lines

MCAN provides two interrupt lines: MCAN\_INT0 and MCAN\_INT1. By programming the MCAN\_ILE.EINT0 and MCAN\_ILE.EINT1 bits, these two interrupt lines can be enabled or disabled independently.

## 37.3.2 Pin Description

Table 37-1 MCAN Pin Description

| Pin Name | Direction | Description       |
|----------|-----------|-------------------|
| MCAN_RX  | Input     | MCAN receive pin  |
| MCAN_TX  | Output    | MCAN transmit pin |

## 37.3.3 Working Mode

### 37.3.3.1 Software Initialization

Software initialization is started by setting MCAN\_CCCR.INIT. This bit is also set by a software reset, hardware reset, or upon entering Bus\_Off state. When MCAN\_CCCR.INIT is set, both incoming and outgoing messages on the CAN bus stop and the state of the MCAN\_TX pin becomes recessive (high). The counters of the Error Management Logic (EML) remain unchanged. Setting MCAN\_CCCR.INIT does not change any configuration registers. Clearing MCAN\_CCCR.INIT to zero completes software initialization, after which the bit stream processing unit (BSP) waits for a sequence of 11 consecutive recessive bits to appear on the bus (Bus\_Idle) to synchronize itself with the data transmission on the CAN bus before participating in bus activities and starting message transmission.

The MCAN configuration registers can be accessed only when both MCAN\_CCCR.INIT and MCAN\_CCCR.CCE are set. The MCAN configuration registers are shown in the following table.

Table 37-2 MCAN Configuration Register List

| Register   | Description                                                      |
|------------|------------------------------------------------------------------|
| MCAN_DBTP  | MCAN Data Bit Time and Prescaler Register                        |
| MCAN_TEST  | MCAN Test Register                                               |
| MCAN_RWD   | MCAN RAM Watchdog Register                                       |
| MCAN_CCCR  | MCAN CC Control Register                                         |
| MCAN_NBTP  | MCAN Nominal Bit Time and Prescaler Register                     |
| MCAN_TSCC  | MCAN Timestamp Counter Configuration Register                    |
| MCAN_TOCC  | MCAN Timeout Counter Configuration Register                      |
| MCAN_TDCR  | MCAN Transmitter Delay Compensation Register                     |
| MCAN_GFC   | MCAN Global Filter Configuration Register                        |
| MCAN_SIDFC | MCAN Standard ID Filter Configuration Register                   |
| MCAN_XIDFC | MCAN Extended ID Filter Configuration Register                   |
| MCAN_XIDAM | MCAN Extended ID and Mask Register                               |
| MCAN_RXF0C | MCAN Receive FIFO0 Configuration Register                        |
| MCAN_RXBC  | MCAN Receive Buffer Configuration Register                       |
| MCAN_RXF1C | MCAN Receive FIFO1 Configuration Register                        |
| MCAN_RXESC | MCAN Receive Buffer and FIFO Element Size Configuration Register |
| MCAN_TXBC  | MCAN Transmit Buffer Configuration Register                      |
| MCAN_TXESC | MCAN Transmit Buffer Element Size Configuration Register         |
| MCAN_TXEFC | MCAN Transmit Event FIFO Configuration Register                  |

MCAN\_CCCR.CCE can be set or cleared only when MCAN\_CCCR.INIT is set, and is automatically cleared when MCAN\_CCCR.INIT is cleared.

When MCAN\_CCCR.CCE is set, the following registers will be reset:

- MCAN\_HPMS: High priority message status
- MCAN\_RXF0S: Receive FIFO 0 status
- MCAN\_RXF1S: Receive FIFO 1 status
- MCAN\_TXFQS: Transmit FIFO/queue status
- MCAN\_TXBRP: Transmit buffer request pending
- MCAN\_TXBTO: Transmit buffer transmission occurs
- MCAN\_TXBCF: Transmit buffer cancel completed
- MCAN\_TXEFS: Transmit event FIFO status
- MCAN\_TXBAR: Transmit buffer add request
- MCAN\_TXBCR: Transmit buffer cancel request

The host can set MCAN\_CCCR.TEST and MCAN\_CCCR.MON only when MCAN\_CCCR.INIT and MCAN\_CCCR.CCE are both set. The host can reset MCAN\_CCCR.TEST and MCAN\_CCCR.MON at any time. MCAN\_CCCR.DAR can be set or cleared only when both MCAN\_CCCR.INIT and MCAN\_CCCR.CCE are set.

### 37.3.3.2 Normal Operation

After the MCAN has completed initialization and the MCAN\_CCCR.INIT bit is cleared, the MCAN synchronizes itself with the CAN bus and becomes ready for communication.

When receiving messages, those that pass the receive filters (including message ID and DLC) are stored in a dedicated receive buffer, receive FIFO0, or receive FIFO1.

When transmitting messages, the dedicated transmit buffers and/or the transmit FIFO (queue) must be initialized or updated first. Automatic transmission in response to a received remote frame is not supported.

### 37.3.3.3 CAN FD Operation

There are two types of CAN FD frame transmission. The first is a CAN FD frame without bit rate switching. The second is a CAN FD frame with bit rate switching, in which the control field, data field and CRC field are sent at a higher bit rate than the start and end of the frame.

The r0 bit in the Classical CAN standard frame (after the IDE bit, a reserved bit in the standard frame format) and the r1 bit in the extended frame (after the RTR bit, the first reserved bit in the extended frame format) are decoded as the FDF bit in the CAN FD frame format. The FDF bit is recessive (logic 1) to indicate a CAN FD frame and dominant (logic 0) to indicate a Classic CAN frame. In the CAN FD frame, the two bits res and BRS (Bit Rate Switch) after the FDF bit determine whether to switch the bit rate in the CAN FD frame, and indicate that the bit rate has been switched through res explicit and BRS implicit. The implicit encoding of the res bit is reserved for future protocol extensions. If the FDF bit and the res bit in the frame received by MCAN are both recessive, a protocol exception event will be issued by setting MCAN\_PSR.PXE. If protocol exception handling is enabled (MCAN\_CCCR.PXHD=0), the MCAN will change the operating state from receiving (MCAN\_PSR.ACT=0b10) to synchronizing (MCAN\_PSR.ACT=0b00) at the next sampling point. If protocol exception handling is disabled (MCAN\_CCCR.PXHD=1), the MCAN will treat the recessive res bit as a format error and will respond with an error frame.

CAN FD mode is enabled by programming MCAN\_CCCR.FDOE. If MCAN\_CCCR.FDOE=1, the sending and receiving of CAN FD frames will be enabled. Classic CAN frames can always be sent and received. Whether a CAN FD frame or a Classical CAN frame is transmitted is determined by the FDF bit in the respective transmit buffer element. If MCAN\_CCCR.FDOE=0, all received frames are treated as Classical CAN frames. As a result, reception of a CAN FD frame will trigger an error frame. If CAN FD mode is disabled, even if the FDF bit in the transmit buffer element is set, a CAN FD frame will not be transmitted. The MCAN\_CCCR.FDOE and MCAN\_CCCR.BRSE bits can only be modified when both MCAN\_CCCR.INIT and MCAN\_CCCR.CCE are set.

If MCAN\_CCCR.FDOE=0, the setting of the FDF and BRS bits are ignored, and the frame is transmitted in Classical CAN format. If MCAN\_CCCR.FDOE=1 and MCAN\_CCCR.BRSE=0, only the FDF bit in the transmit buffer is evaluated. If MCAN\_CCCR.FDOE=1 and MCAN\_CCCR.BRSE=1, transmission of CAN FD frames with bit rate switching is enabled. In this case, all transmit buffer elements with both FDF and BRS bits set will be transmitted as CAN FD frames with bit rate switching.

It is recommended to switch modes during CAN operation only under the following condition:

- The failure rate in the CAN FD data phase is significantly higher than the failure rate in the CAN FD arbitration phase. In this case, bit rate switching for CAN FD transmission should be disabled.
- During system startup, all nodes transmit classical CAN messages until communication using CAN FD format is verified. Once verification is complete, all nodes switch to CAN FD operation.
- In CAN Partial Networking, wake-up messages must be transmitted using Classical CAN format.

- During EOL programming (End-of-line programming), not all nodes support CANFD, and non-CANFD nodes will remain in silent mode until the end of programming. Afterward, all nodes switch back to Classical CAN communication.

In the CAN FD format, DLC codes 0 to 8 have the same encoding (i.e., corresponding data byte lengths) as in Classical CAN, while DLC codes 9 to 15 differ from Classical CAN, as shown in the table below.

Table 37-3 DLC Encoding in MCAN

| DLC Code        |               | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9  | 10 | 11 | 12 | 13 | 14 | 15 |
|-----------------|---------------|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|----|
| Data Byte Count | Classical CAN | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 8  | 8  | 8  | 8  | 8  | 8  | 8  |
|                 | CAN FD        | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 12 | 16 | 20 | 24 | 32 | 48 | 64 |

In CAN FD frames, if the BRS bit is recessive, the bit timing will switch within the frame after the BRS (bit rate switching) bit. Before the BRS bit, during the CAN FD arbitration phase, the bit timing follows the definition in the MCAN\_NBTP (Nominal Bit Timing & Prescaler Register). During the following CAN FD data phase, the bit timing follows the definition in the MCAN\_DBTP (Data Bit Timing & Prescaler Register). The bit timing will switch back to the data phase bit timing at the CRC delimiter or when an error is detected, whichever occurs first.

The maximum configurable bit rate in the CAN FD data phase depends on the CAN communication clock frequency. For example, if the CAN communication clock frequency is 20 MHz, the shortest configurable bit time is 4 time quanta (tq), which results in a data phase bit rate of 5Mbps.

In both CAN FD frames with bit rate switching and CAN FD frames without bit rate switching, the ESI (Error Status Indicator) bit is set based on the error status of the transmitting node at the time of transmission. If the transmitting node is in error passive state, the ESI bit is transmitted recessive. Otherwise, it is transmitted dominant.

#### 37.3.3.4 Transmit Delay Compensation

In the CAN FD data phase, only one node transmits, while all other nodes are receivers. The length of the bus does not affect this. When transmitting through the MCAN\_TX pin, the MCAN receives the transmitted data from its local CAN transceiver via the MCAN\_RX pin. The received data is delayed due to the transmission delay, and if the delay exceeds TSEG1 (the time segment before the sample point), a bit error will be detected. To allow the data phase bit time to be shorter than the transmission delay, delay compensation is introduced. Without delay compensation, the bit rate in the CAN FD frame data phase would be limited by the transmission delay.

The MCAN protocol unit implements a delay compensation mechanism to compensate for the transmission delay, enabling higher bit rates during the CAN FD data phase without being affected by the specific CAN transceiver's delay.

To check for bit errors in the data phase of the transmitting node, the delayed transmitted data is compared with the received data at the second sample point (SSP). If a bit error is detected, the transmitting node will react to the bit error at the next regular sample point. In the arbitration phase, delay compensation is always disabled.

Transmit delay compensation supports configurations where the data bit time is shorter than the transmission delay. ISO 11898-1:2015 provides a detailed description of this mechanism, which is enabled by setting MCAN\_DBTP.TDC.

At the second sample point (SSP), the received bit is compared with the transmitted bit. The position of the SSP is defined as the delay from the MCAN\_TX pin through the transceiver to the MCAN\_RX pin, added to the transmission delay compensation offset configured by MCAN\_TDCR.TDCO. The transmission delay compensation offset is used to adjust the position of the SSP within the received bit (for example, half the bit time in the data phase). The position of the second sample point is rounded down to the nearest mtq (Minimum Time Quantum, which is one MCAN communication clock period).

The value of the actual transmission delay compensation is displayed in MCAN\_PSR.TDCV. When MCAN\_CCCR.INIT is set, MCAN\_PSR.TDCV is cleared; When MCAN\_DBTP.TDC is set, MCAN\_PSR.TDCV is updated each time an FD frame is transmitted.

For transmit delay compensation implemented in MCAN, the following boundary conditions must be considered:

- The measured delay from MCAN\_TX to MCAN\_RX, plus the configured transmission delay compensation offset (MCAN\_TDCR.TDCO), must be less than 6 bit times in the data phase.
- The measured delay from MCAN\_TX to MCAN\_RX, plus the configured transmission delay compensation offset (MCAN\_TDCR.TDCO), must be less than or equal to 127 mtq. If this sum exceeds 127 mtq, the transmit delay compensation uses the maximum value of 127 mtq.
- The data phase ends at the CRC delimiter sample point, after which the received bits will not be checked at the SSP.

If MCAN\_DBTP.TDC=1 is programmed to enable transmit delay compensation, measurement starts at the falling edge between the FDF bit and res bit of each CAN FD frame. When this edge is detected at the transmitting node's MCAN\_RX pin, the measurement stops. The resolution of this measurement is one mtq.

Figure 37-2 Transceiver Delay Measurement

To avoid dominant glitches in the received FDF bit, the delay compensation measurement should end before the falling edge of the received res bit, which would otherwise cause the SSP position to

advance prematurely. This can be achieved by programming MCAN\_TDCR.TDCF to enable a transmit delay compensation filtering window, which defines the minimum value of the SSP position. A dominant edge on the MCAN\_RX pin will cause the SSP position to advance further, but this will be ignored in the context of the transmit delay measurement. Measurement stops when the SSP position is at least MCAN\_TDCR.TDCF and the MCAN\_RX pin is at a low level.

**Note**

The transmit delay used by MCAN is a real-time measured value, and it does not support configuring a fixed transmit delay.

### 37.3.3.5 Restricted Working Mode

In restricted working mode, the node is able to receive data frames and remote frames, and can acknowledge active frames, but it will not send data frames, remote frames, active error frames, or overload frames. In the event of an error or overload condition, the node will not send a dominant bit but will wait for the bus idle condition to re-synchronize with the CAN communication. When error recording occurs (MCAN\_TDCR.CEL), the error counters (MCAN\_TDCR.REC, MCAN\_TDCR.TEC) are frozen. The host can set the MCAN\_CCCR.ASM bit to configure MCAN to restricted working mode, but this can only be done when both MCAN\_CCCR.CCE and MCAN\_CCCR.INIT are set to 1. The MCAN\_CCCR.ASM bit can be cleared at any time by the host.

If the transmit processing unit is unable to read data from the message RAM in time, the node will automatically enter restricted working mode. To exit restricted working mode, the host CPU must clear the MCAN\_CCCR.ASM bit.

Restricted working mode can be used to accommodate applications with different CAN bit rates. In this case, the application will test different bit rates and exit restricted working mode after receiving a active frame.

**Note**

Restricted working mode should not be used in conjunction with loopback mode (either internal or external).

### 37.3.3.6 Bus Monitoring Mode

By setting MCAN\_CCCR.MON to 1, the MCAN is configured to bus monitoring mode. In bus monitoring mode (see ISO 11898-1:2015, 10.14 Bus Monitoring), MCAN is able to receive active data frames and remote frames, but it cannot initiate transmission. In this mode, MCAN sends dominant bits on the CAN bus. If MCAN needs to send a recessive bit (such as the ACK bit, overload flag, or active error flag), that bit is internally rerouted to allow MCAN to listen to the recessive bit, while the CAN bus remains in the dominant state. In bus monitoring mode, the MCAN\_TXBRP register remains in a reset state.

Bus monitoring mode can be used to analyze traffic on the CAN bus without causing interference on the bus by transmitting recessive bits. The following figure shows the connection between MCAN\_TX and MCAN\_RX signals and MCAN in bus monitoring mode.

Figure 37-3 Pin Control in Bus Monitoring Mode

### 37.3.3.7 Disable Automatic Retransmission (DAR) Mode

According to the CAN specification (see ISO 11898-1:2015, 8.3.4 Recovery Management), MCAN can automatically retransmit frames that fail arbitration or are disturbed during transmission. By default, automatic retransmission is enabled.

In DAR mode, all transmissions that are initiated on the CAN bus will be automatically canceled. The transmission request pending bit in the transmission buffer MCAN\_TXBRP.TRPx will be cleared after a successful transmission. If the transmission is canceled before it begins, due to arbitration failure, or if an error occurs during the frame transmission, the bit will also be reset.

- Successful transmission:
  - ▶ The corresponding transmission buffer transmission occurred bit MCAN\_TXBTO.TOx is set.
  - ▶ The corresponding transmission buffer cancellation completed bit MCAN\_TXBCF.CFx is not set.
- Transmission canceled but still successful:
  - ▶ The corresponding transmission buffer transmission occurred bit MCAN\_TXBTO.TOx is set.
  - ▶ The corresponding transmission buffer cancellation completed bit MCAN\_TXBCF.CFx is set.
- Arbitration failure or frame transmission disturbed:
  - ▶ The corresponding transmission buffer transmission occurred bit MCAN\_TXBTO.TOx is not set.
  - ▶ The corresponding transmission buffer cancellation completed bit MCAN\_TXBCF.CFx is set.

If the frame transmission is successful and event storage for transmission is enabled, the transmission event will be written to the transmission event FIFO element, where the event type ET=0b10 (indicating transmission even if canceled).

### 37.3.3.8 Power-Down (Sleep Mode)

MCAN can be set to Power-down mode through the CC Control Register MCAN\_CCCR.CSR. As long as the clock stop request is active, the MCAN\_CCCR.CSR bit will read as 1.

After all pending transmission requests are completed, MCAN will wait until the bus idle state is detected. Once the bus idle state is detected, MCAN will set MCAN\_CCCR.INIT to 1 to prevent any further CAN transmission. Then, MCAN will confirm that it is ready to enter Power-down mode by setting MCAN\_CCCR.CSA to 1. Before the module clock (both control logic clock and communication clock) is turned off, the registers are still accessible, but MCAN\_CCCR.INIT remains set to 1.

**Note**

In cases of severe interference on the CAN bus, the bus may never reach the idle state, and therefore MCAN will not set MCAN\_CCCR.INIT. This situation can be detected by polling the MCAN\_PSR.ACT bit. If MCAN does not enter the idle state, software can write CCCR.INIT=1, which will immediately stop MCAN's CAN communication, regardless of whether transmission or reception is in progress.

To exit Power-down mode, the application must first enable the module clock before resetting the CC control register flag MCAN\_CCCR.CSR. MCAN will confirm that the clock is enabled by resetting MCAN\_CCCR.CSA. Afterward, the application can restart CAN communication by resetting MCAN\_CCCR.INIT.

### 37.3.3.9 Test Pattern

To enable write access to the MCAN Test Register MCAN\_TEST (refer to "[MCAN Test Register \(MCAN\\_TEST\)](#)"), the MCAN\_CCCR.TEST bit must be set to 1, allowing the configuration of test modes and test functions.

By programming MCAN\_TEST.TX, the MCAN\_TX pin can perform four output functions. In addition to the default serial data output function, it can also drive the CAN sampling point signal to monitor the bit timing of the MCAN and output a constant dominant or recessive level. The actual value of the MCAN\_RX pin can be read from MCAN\_TEST.RX. These two functions (MCAN\_TEST.TX and MCAN\_TEST.RX) can be used to check the physical layer of the CAN bus.

Due to the synchronization mechanism between the CAN communication clock and the control logic clock, there may be a delay of several control logic clock periods from configuring MCAN\_TEST.TX to implementing the specified function on the MCAN\_TX pin. This also applies to reading the value of MCAN\_RX through MCAN\_TEST.RX.

**Note**

Test mode is intended for production testing and self-diagnostics only. Software control of the MCAN\_TX pin will interfere with all CAN protocol functions. Test mode is not recommended for use in actual applications.

### 37.3.3.10 Loop Mode

#### External Loopback Mode

To set MCAN to external loopback mode, configure MCAN\_TEST.LBCK to 1. In this mode, MCAN processes its own transmitted messages as received messages, and stores them in the receive buffer or receive FIFO, provided these messages pass the receive filtering. In external loopback mode, the MCAN\_TX signal is internally fed back to the receive processing unit. The actual value at the MCAN\_RX input pin is ignored.

Figure 37-4 External Loopback Mode Pin Control

This mode is used for hardware self-test. To prevent external influences, MCAN ignores ACK errors in loopback mode (e.g., when a recessive bit is sampled in the ACK field of a data or remote frame). In this mode, the signal output by MCAN\_TX is directly fed back to the receiving processing unit internally, and the actual value of the MCAN\_RX input pin is ignored. The sent message can be monitored from the pin MCAN\_TX.

#### Internal Loopback Mode

To set MCAN to internal loopback mode, configure both MCAN\_TEST.LBCK and MCAN\_CCCR.MON to 1. This mode is also referred to as "Hot Selftest," meaning MCAN can be tested without affecting the ongoing CAN system. In this mode, the MCAN\_RX pin is disconnected from MCAN, and the MCAN\_TX pin remains recessive (dominant). In this mode, the MCAN\_RX pin is disconnected from MCAN, and the MCAN\_TX pin remains recessive (dominant).

Figure 37-5 Pin Control for Internal Loopback Mode

### 37.3.4 Timestamp Generation

MCAN provides a 16-bit cyclic counter to generate internal timestamps. The counting time unit can be configured to 1-16 times the CAN bit time through the prescaler MCAN\_TSCC.TCP. The counter value can

be read through MCAN\_TSCV.TCV. A write access to the register MCAN\_TSCV resets the counter to 0. The interrupt flag MCAN\_IR.TSW is set when the timestamp counter periods.

When SOF (Start Of Frame) is received or sent, the count value is captured and stored in the timestamp part of the receive buffer or receive FIFO (RXTS[15:0]) or transmit event FIFO (TXTS[15:0]) element.

### 37.3.5 Timeout Counter

The MCAN provides a 16-bit timeout counter to indicate timeout conditions for receive FIFO0, receive FIFO1 and transmit event FIFO. It operates as a down counter and, like the timestamp counter, uses a prescaler controlled by MCAN\_TSCC.TCP. The timeout counter is configured via register MCAN\_TOCC. The actual counter value can be read from MCAN\_TOCV.TOC. The timeout counter is started only when MCAN\_CCCR.INIT=0. The timeout counter stops counting when MCAN\_CCCR.INIT=1, e.g. when the CAN enters the Bus\_Off state.

The operating mode is selected via MCAN\_TOCC.TOS. When operating in continuous mode, the counter starts when MCAN\_CCCR.INIT is reset. Writing to MCAN\_TOCV presets the counter to the value configured by MCAN\_TOCC.TOP and continues counting down.

When the timeout counter is controlled by one of the FIFOs, an empty FIFO presets the counter to the value configured by MCAN\_TOCC.TOP. After the first FIFO element is stored, it starts counting down. Writing to MCAN\_TOCV has no effect.

When the counter reaches 0, the interrupt flag MCAN\_IR.TOO is set. In continuous mode, the counter restarts immediately after reaching MCAN\_TOCC.TOP.

#### Note

The clock signal for the timeout counter comes from the CAN core sample point signal. Therefore, the time at which the timeout counter is decremented may differ due to the CAN core synchronization (resynchronization) mechanism. If the bit rate switching feature is used in CAN FD, the timeout counter counts with different clocks in the Arbitration phase and the Data phase.

### 37.3.6 Reception Processing

The receive processing unit controls receive filtering, transfer of received messages to the receive buffer or one of the two receive FIFOs, and receive FIFO put and get indexes.

#### 37.3.6.1 Receive Filtering

MCAN is able to configure two sets of receive filters, one for standard IDs and one for extended IDs. These two sets of filters can be assigned to the receive buffer, receive FIFO0 or receive FIFO1. For receive filtering, each filter list is compared starting from the 0th element until the first matching element. Receive filtering stops at the first matching element. The remaining filter elements are not evaluated for this message.

- Key features include:
  - ▶ Each filter element can be configured as
    - ◆ ID range filter (start and end range)
    - ◆ Filters for one or two dedicated IDs
    - ◆ Classic filter with ID bit masking
  - ▶ Each filter element can be configured to implement receive filtering or reject filtering
  - ▶ Each filter element can be enabled/disabled individually
  - ▶ Filter elements are compared in order and execution stops after the first matching filter element

- Related configuration register bits:
  - ▶ Global filter configuration (MCAN\_GFC)
  - ▶ Standard ID filter configuration (MCAN\_SIDFC)
  - ▶ Extended ID filter configuration (MCAN\_XIDFC)
  - ▶ Extended ID and operation mask (MCAN\_XIDAM)
- Depending on the configuration of the filter element (SFEC/EFEC), one of the following actions is triggered when a match occurs:
  - ▶ Store the received frame in receive FIFO0 or FIFO1
  - ▶ Store the received frame in the receive buffer
  - ▶ Reject the received frame
  - ▶ Set the high priority message interrupt flag MCAN\_IR.HPM to 1
  - ▶ Set the high priority message interrupt flag MCAN\_IR.HPM to 1 and store the received frame in receive FIFO0 or FIFO1

After receiving the complete ID, receive filtering begins. After the reception filtering is completed, if a matching reception buffer or reception FIFO is found, the message processing unit will start writing the received message data in the form of 32 bits into the matching reception buffer or reception FIFO. If the CAN protocol controller detects an error condition (e.g. CRC error), the message is discarded with the following effects:

- Receive buffer
 

The new data flag of the matching receive buffer is not set, but the receive buffer is (partially) overwritten with the received data. For error types, see MCAN\_PSR.LEC and MCAN\_PSR.DLEC.
- Receive FIFO
 

The put index of the matching receive FIFO is not updated, but the associated receive FIFO element is (partially) overwritten with the received data. For error types, see MCAN\_PSR.LEC and MCAN\_PSR.DLEC. Receive FIFO If the matching receive FIFO operates in overwrite mode, the boundary conditions described in Receive FIFO overwrite mode must be taken into account.

#### Note

When the received message is written to one of the two receive FIFOs or to the receive buffer, the unmatched received ID is stored independently of the used filter. The process of receive filtering depends strongly on the order of the configured filter elements.

### 37.3.6.2 ID Range Filter

This filter checks all received frames for a match with the message IDs in the range defined by SF1ID/SF2ID and EF1ID/EF2ID. When range filtering is used with extended frames, there are two possible cases:

- EFT=0b00: The message ID of the received frame is ANDed with the extended ID and the operation mask (MCAN\_XIDAM) before the range filter is applied
- EFT=0b11: Do not use the extended ID and mask (MCAN\_XIDAM) for range filtering

### 37.3.6.3 Dedicated ID Filter

The filter element can be configured to filter on one or two specific message IDs. To filter a specific message ID, the filter element must be configured with SF1ID=SF2ID and EF1ID=EF2ID.

### 37.3.6.4 ID Bit Mask Filter

ID bit mask filtering is used to filter groups of message IDs by masking certain bits of the received message ID. When performing ID bit mask filtering, SF1ID/EF1ID is used as a message ID filter and SF2ID/EF2ID is used as a filter ID mask.

Bits that are 0 in the ID mask mask the corresponding bits of the configured ID filter, i.e., the value of the received message ID at that bit position is not compared with the value of the corresponding bit of the received filter, only the bits of the received message ID for which the corresponding mask bit is 1 are compared.

If all mask bits are 1, a match occurs only if the received message ID and the message ID filter are exactly the same. If all mask bits are 0, all message IDs match.

### 37.3.6.5 Standard Message ID Filtering

The following diagram illustrates the filtering process for a standard message ID (11-bit ID). "Standard Message ID Filter Element" describes the standard message ID filter element.

Figure 37-6 Standard Message ID Filter Path

Under the control of the global filter configuration register (MCAN\_GFC) and the standard ID filter configuration register (MCAN\_SIDFC), the ID, remote transmission request bit (RTR), and ID extension bit (IDE) of the received message are compared to the configured list of filter elements.

### 37.3.6.6 Extended Message ID Filtering

The following figure describes the filtering process for extended message IDs (29-bit IDs). "Extended Message ID Filter Elements" describes the extended message ID filter elements.

Figure 37-7 Extended Message ID Filter Path

The received message ID, remote transmission request bit (RTR), and ID extension bit (IDE) are compared to the configured filter element list under the control of the global filter configuration register (MCAN\_GFC) and the extended ID filter configuration register (MCAN\_XIDFC). The extended ID and mask (MCAN\_XIDAM) is ANDed with the received ID before executing the filter list.

### 37.3.6.7 Receive FIFO

Receive FIFO0 and receive FIFO1 can store up to 64 elements each (the actual number of elements depends on the capacity of the message RAM). The configuration of the two receive FIFOs is done via registers MCAN\_RXF0C and MCAN\_RXF1C.

Messages that pass the receive filter are transferred to the receive FIFO configured with the matching filter element. For a description of the filter mechanism that can be used for receive FIFO0 and receive FIFO1, see "Receive Filtering". "Receive Buffer and FIFO Elements" describes the receive buffer and FIFO elements.

To avoid receive FIFO overflow, a receive FIFO watermark can be used. When the receive FIFO fill level reaches the receive FIFO watermark configured by MCAN\_RXFnC.FnWM, the interrupt flag MCAN\_IR.RFnW is set. When the put index and get index of the receive FIFO meet, the receive FIFO full condition occurs, the flag bit MCAN\_RXFnS.FnF is set, and the interrupt flag bit MCAN\_IR.RFnF is set.

Figure 37-8 Receive FIFO Status

When reading a message from the receive FIFO, the receive FIFO get index `MCAN_RXFnS.FnGI` multiplied by the FIFO element size (words), multiplied by 4, must be added to the start address `MCAN_RXFnC.FnSA`.

Table 37-4 Receive buffer and FIFO element size

| <code>RXESC.RBDS[2:0]</code><br><code>RXESC.FnDS[2:0]</code> | Data Field (Bytes) | Element Size (Words) |
|--------------------------------------------------------------|--------------------|----------------------|
| 0b000                                                        | 8                  | 4                    |
| 0b001                                                        | 12                 | 5                    |
| 0b010                                                        | 16                 | 6                    |
| 0b011                                                        | 20                 | 7                    |
| 0b100                                                        | 24                 | 8                    |
| 0b101                                                        | 32                 | 10                   |
| 0b110                                                        | 48                 | 14                   |
| 0b111                                                        | 64                 | 18                   |

### 37.3.6.8 Receive FIFO Blocking Mode

Receive FIFO blocking mode is configured by `MCAN_RXFnC.FnOM=0`, which is the default operating mode of the receive FIFO.

When the receive FIFO full condition is reached (`MCAN_RXFnS.FnPI=MCAN_RXFnS.FnGI`), the flag bit `RXFnS.FnF=1` and the interrupt flag `MCAN_IR.RFnF=1`. At this time, the MCAN will not continue to write

messages to the corresponding receive FIFO unless the message is read from the corresponding receive FIFO and its fetch index has been incremented.

If a message is received when the corresponding receive FIFO is full, this message will be discarded and the message loss will be indicated by `MCAN_RXFnS.RFnL=1`. In addition, the interrupt flag `MCAN_IR.RFnL` will also be set.

### 37.3.6.9 Receive FIFO Overwrite Mode

Receive FIFO overwrite mode is configured by `MCAN_RXFnC.FnOM=1`.

When the receive FIFO full condition is reached (`MCAN_RXFnS.FnPI=MCAN_RXFnS.FnGI`), the flag bit `RXFnS.FnF=1`. At this time, the next message received by the FIFO will overwrite the oldest received message, and both the put index and the get index will increase by 1.

If the receive FIFO operates in overwrite mode and the receive FIFO is full, the receive FIFO elements should be read from at least the get index plus 1. This is because when the CPU is reading a message from the message RAM, a received message is being written to the message RAM, which may cause the data read by the CPU to be inconsistent with the actual data. Adding an offset to the get index when reading data from the receive FIFO can avoid this problem. The offset depends on the speed at which the CPU accesses the receive FIFO. The figure below shows that the get index offset is 2 when reading the receive FIFO. In this case, the two messages stored in elements 1 and 2 are lost.

Figure 37-9 Receive FIFO Overflow Processing

After reading data from the receive FIFO, the number of the last element read must be written into the receive FIFO confirmation index register `MCAN_RXFnA.FnA` so that the incremented acquisition index points to the next element. If the put index does not increase to the receive FIFO element number, the receive FIFO full flag will be reset (`MCAN_RXFnS.FnF=0`).

### 37.3.6.10 Dedicated Receive Buffer

The MCAN supports up to 64 dedicated receive buffers. The starting address of the dedicated receive buffer is configured via `RXBC.RBSA`.

To use the dedicated receive buffer, the SFEC bits of the standard message ID filter element must be configured to 0b111 and the SFID2 bits to 0b00 for standard ID messages (see "[Standard Message ID Filter Element](#)"); for extended ID messages, the EFEC bits of the extended message ID filter element must be configured to 0b111 and the EFID2 bits to 0b00 (see "[Extended Message ID Filter Element](#)"). The following table shows an example filter configuration for a dedicated receive buffer.

After a received message is accepted by a filter element, it is stored in the receive buffer in the message RAM referenced by the filter element. The storage format is the same as for the receive FIFO element. In addition, the flag MCAN\_IR.DRX in the interrupt register (message stored in the dedicated receive buffer) is set to 1.

**Table 37-5 Receive Buffer Filter Configuration Example**

| Filter Elements | SFID1[10:0]  | SFID2[10:9] | SFID2[5:0] |
|-----------------|--------------|-------------|------------|
|                 | EFID1[28:0]  | EFID2[10:9] | EFID2[5:0] |
| 0               | ID Message 1 | 0b00        | 0b000000   |
| 1               | ID Message 2 | 0b00        | 0b000001   |
| 2               | ID Message 3 | 0b00        | 0b000010   |

After the last word of the matching received message is written to the message RAM, the corresponding new data flag in register MCAN\_NDAT1/MCAN\_NDAT2 is set. As long as the new data flag remains set, the corresponding receive buffer is locked to prevent it from being updated with a new matching message. The new data flag must be reset by the host writing 1 to the corresponding bit.

When the receive buffer new data flag is set, its corresponding message ID filter element will not perform receive filtering, and other filter elements will continue to perform receive filtering. Other message ID filter elements may cause the received message to be stored in another receive buffer or receive FIFO, or rejected, depending on the filter configuration.

### 37.3.6.11 Receive Buffer Processing

- Reset interrupt flag MCAN\_IR.DRX
- Read new data register
- Read message from message RAM
- Reset new data flag of processed message

### 37.3.6.12 Filtering Debug Messages

To filter debug messages, configure a standard or extended message ID filter element for each of the three debug messages. To enable the filter element to filter debug messages, SFEC/EFEC must be programmed to 0b111. In this case, SFID1/SFID2 and EFID1/EFID2 have different meanings (see "[Standard Message ID Filter Element](#)" and "[Extended Message ID Filter Element](#)"). SFID2/EFID2[10:9] controls the debug message processing state machine, while SFID2/EFID2[5:0] controls the storage location of the received debug message. The following table shows an example of the debug message filter configuration.

When storing debug messages, the corresponding new data flag and MCAN\_IR.DRX are not set, and the reception of debug messages can be monitored through MCAN\_RXF1S.DMS.

Table 37-6 Debug Message Filter Configuration Example

| Filter Elements | SFID1[10:0]<br>EFID1[28:0] | SFID2[10:9]<br>EFID2[10:9] | SFID2[5:0]<br>EFID2[5:0] |
|-----------------|----------------------------|----------------------------|--------------------------|
| 0               | ID Debug Message A         | 0b01                       | 0b111101                 |
| 1               | ID Debug Message B         | 0b10                       | 0b111110                 |
| 2               | ID Debug Message C         | 0b11                       | 0b111111                 |

### 37.3.7 Transmission Processing

The transmit processing unit handles the send requests for the dedicated transmit buffers, the transmit FIFOs and the transmit queues. It controls the transmission of the send messages to the CAN core, puts and gets the index and transmit event FIFO. Up to 32 send buffers can be set for message transmission, each of which can be independently configured with the send mode (Classic CAN mode or CAN FD mode). For a description of the send buffers, see "[Transmit Buffer Elements](#)". The following table describes the possible configurations of the send frame.

Table 37-7 Possible configurations of the send frame

| MCAN_CCCR |      | Transmit Buffer Elements |        | Transmit Frame                |
|-----------|------|--------------------------|--------|-------------------------------|
| BRSE      | FDOE | FDF                      | BRS    |                               |
| Ignore    | 0    | Ignore                   | Ignore | Classic CAN                   |
| 0         | 1    | 0                        | Ignore | Classic CAN                   |
| 0         | 1    | 1                        | Ignore | FD without bit rate switching |
| 1         | 1    | 0                        | Ignore | Classic CAN                   |
| 1         | 1    | 1                        | 0      | FD without bit rate switching |
| 1         | 1    | 1                        | 1      | FD with bit rate switching    |

#### Note

AUTOSAR requires at least three transmit queue buffers and supports transmission cancellation.

When the Transmit Buffer Request Pending Register (MCAN\_TXBRP) is updated, the transmission handler initiates a transmit scan to check for the highest priority pending transmission request (i.e., the transmit buffer with the smallest message ID). The conditions for MCAN\_TXBRP to be updated are that a transmit buffer is sent completely, or the host adds a transmit request by writing MCAN\_TXBAR, or the host cancels a pending transmission by writing MCAN\_TXBCR.

#### 37.3.7.1 Transmit Pause

The Transmit Pause feature is used in CAN systems where CAN message IDs are (permanently) assigned to specific values and cannot be easily changed. These message IDs may have a higher CAN arbitration priority than other defined messages, and in certain applications their relative arbitration priorities should be reversed. This may result in a situation where a burst of multiple CAN messages with a higher arbitration priority from one ECU causes the CAN messages of another ECU with a lower arbitration priority to be delayed.

For example, if CAN ECU-1 has this feature enabled and its application software requests to send four messages, after successfully sending the first message it will wait for two CAN bit times of free

bus time before allowing the next requested message to start. If other ECUs have pending messages, they will start sending these messages during the free time without arbitration with the next message from ECU-1. After receiving a message, ECU-1 can start the next transmission as soon as the received message releases the CAN bus.

This feature is controlled via MCAN\_CCCR.TXP. If this bit is set, the MCAN will pause for two CAN bit times after each successful message before starting the next transmission. This allows messages to be sent even if other nodes in the network have lower priority IDs. This feature is disabled by default (MCAN\_CCCR.TXP=0). This feature allows bursts of multiple messages from a single node to be more sparse, preventing the ECU sending lower priority messages from causing the application to mistakenly believe that it has requested too many transmissions.

### 37.3.7.2 Dedicated Transmit Buffer

Dedicated transmit buffers allow messages to be sent entirely under the control of the host CPU. Each dedicated transmit buffer is configured with a specific message ID. If multiple transmit buffers are configured with the same message ID, the message from the buffer with the lowest buffer number is transmitted first. These buffers should be requested for transmission in ascending order, i.e., by requesting the buffer with the lowest number first, or by issuing a single write to MCAN\_TXBAR to request multiple buffers simultaneously.

If the message in a buffer is updated, transmission can be requested by setting the corresponding bit in MCAN\_TXBAR.ARn. A requested transmission will first undergo internal arbitration against messages in the transmit FIFO or transmit queue, based on message ID, followed by external arbitration on the CAN bus. The message is then transmitted according to the arbitration result.

The size of each dedicated transmit buffer element in the message RAM is a configurable number of 32-bit words(4 bytes). Therefore, the starting address of the dedicated transmit buffer in the message RAM is calculated by multiplying the transmit buffer index (0 to 31) by the element size (words), multiplied by 4 (converted to bytes), and then added to MCAN\_TXBC.TBSA.

Table 37-8 Transmit Buffer, FIFO (queue) Element Size

| TXESC.TBDS2[2:0] | Data Field (bytes) | Element Size (words) |
|------------------|--------------------|----------------------|
| 0b000            | 8                  | 4                    |
| 0b001            | 12                 | 5                    |
| 0b010            | 16                 | 6                    |
| 0b011            | 20                 | 7                    |
| 0b100            | 24                 | 8                    |
| 0b101            | 32                 | 10                   |
| 0b110            | 48                 | 14                   |
| 0b111            | 64                 | 18                   |

### 37.3.7.3 Transmit FIFO

Transmit FIFO mode is enabled by configuring MCAN\_TXBC.TFQM to 0. Messages stored in the transmit FIFO are sent starting from the buffer pointed to by the Get Index (MCAN\_TXFQS.TFGI). After each transmission, the Get Index is incremented in a circular manner until the FIFO becomes empty. The transmit FIFO sends messages with the same ID from different transmit buffers in the order in which

they were written. MCAN calculates the number of available (free) transmit FIFO elements (TXFQS.TFFL) by subtracting the Get Index from the Put Index.

New messages must be written starting from the transmit buffer pointed to by the Put Index (MCAN\_TXFQS.TFQPI). Adding a transmit request increments the Put Index to the next available FIFO element. When the Put Index catches up with the Get Index, the FIFO is considered full (MCAN\_TXFQS.TFQF=1). In this state, no further messages should be written to the FIFO until the next message is transmitted and the Get Index is updated.

If a single message is added to the FIFO, its transmission is triggered by writing 1 to the corresponding bit in MCAN\_TXBAR for the buffer at the Put Index.

If multiple messages (e.g., n messages) are added, they are written to n consecutive transmit buffers starting from the Put Index. Transmission is then requested via MCAN\_TXBAR, and the Put Index is incremented circularly by n. The number of transmit requests must not exceed the number of free FIFO elements indicated by MCAN\_TXFQS.TFFL.

If the transmission request for the buffer at the Get Index is canceled, the Get Index is incremented to the next pending transmit buffer, and the FIFO free level (MCAN\_TXFQS.TFFL) is recalculated. Canceling transmission from any other buffer does not affect the Get Index or the FIFO free level.

Each transmit FIFO element in the Message RAM is allocated a number of 32-bit words (4 bytes each). Thus, the start address of the next available FIFO element is calculated as: (Put Index [MCAN\_TXFQS.TFQPI](0-31) × Element Size in words × 4) + MCAN\_TXBC.TBSA.

#### 37.3.7.4 Transmission Sequence

Transmit Queue mode is enabled by configuring MCAN\_TXBC.TFQM to 1. Messages stored in the transmit queue are sent in order of message ID priority, starting from the smallest ID (i.e., the highest priority). If multiple transmit queue buffers are configured with the same message ID, the send order is determined by the buffer indices used to store the messages, which are influenced by the current state of the Put Index and therefore cannot be predicted.

New messages must be written into the transmit buffer pointed to by index MCAN\_TXFQS.TFQPI. The Put Index always points to the lowest-numbered free buffer within the transmit queue. If the transmit queue is full (MCAN\_TXFQS.TFQF=1), the Put Index becomes inactive, and no new messages should be written to the transmit queue until at least one pending transmission request is completed or canceled.

Alternatively, the application can use the MCAN\_TXBRP register instead of the Put Index to write messages into any transmit buffer that does not have a pending transmission request.

Each transmit queue element in Message RAM occupies a certain number of 32-bit words (4 bytes each). Thus, the start address of the next available transmit queue buffer is calculated as: (Put Index [MCAN\_TXFQS.TFQPI](0-31) × Element Size in words × 4) + MCAN\_TXBC.TBSA.

#### 37.3.7.5 Mixed Use of Dedicated Transmit Buffers and Transmit FIFO

In this configuration, the transmit buffers in the Message RAM are divided into two parts: a group of dedicated transmit buffers and a Transmit FIFO. The number of dedicated transmit buffers is configured via MCAN\_TXBC.NDTB. The number of transmit buffers assigned to the Transmit FIFO is configured via MCAN\_TXBC.TFQS. If MCAN\_TXBC.TFQS is set to 0, only dedicated transmit buffers are used.

Figure 37-10 Example of Mixed Configuration of Dedicated Transmit Buffers and Transmit FIFO

#### Transmission Priority

- The transmission unit scans all dedicated transmit buffers with active transmission requests, along with the earliest pending request in the Transmit FIFO (i.e., the buffer pointed to by MCAN\_TXFQS.TFGI).
- The message with the lowest message ID has the highest priority and will be selected for transmission next.

#### 37.3.7.6 Mixed Use of Dedicated Transmit Buffers and Transmit Queue

In this configuration, the transmit buffers in the message RAM are divided into two parts: a set of dedicated transmit buffers and a transmit queue. The number of dedicated transmit buffers is configured via MCAN\_TXBC.NDTB. The number of transmit queue buffers is configured via MCAN\_TXBC.TFQS. If MCAN\_TXBC.TFQS is set to 0, only dedicated transmit buffers are used.

Figure 37-11 Example of Mixed Configuration of Dedicated Transmit Buffers and Transmit Queue

#### Transmission Priority

- The transmission unit scans all dedicated transmit buffers and transmit queue buffers with active transmission requests.
- The buffer with the lowest message ID has the highest priority and its message will be transmitted next.

#### 37.3.7.7 Transmission Cancellation

MCAN supports transmission cancellation, which particularly useful for gateway applications and AUTO-SAR-based systems. To cancel a transmission request from either a dedicated transmit buffer or a

transmit queue buffer, the host must write a 1 to the corresponding bit (based on the buffer index) in the MCAN\_TXBCR register. Transmission cancellation is not supported in transmit FIFO mode.

Upon successful cancellation, the corresponding bit in the MCAN\_TXBCF register is set to 1.

If a cancellation is requested while the buffer is in the process of transmitting, the corresponding bit in the MCAN\_TXBRP register remains set to 1 as long as the transmission is active. If the transmission completes successfully, the respective bits in both MCAN\_TXBTO and MCAN\_TXBCF will be set to 1. If the transmission fails, it will not be retried, and only the corresponding bit in MCAN\_TXBCF is set.

**Note**

In cases where a pending transmission is cancelled before it begins, a short delay window may exist during which no message is transmitted—even if another message is pending in the node. This allows another node on the CAN network to transmit a message, which may have a lower priority than the second message in the original node.

### 37.3.7.8 Transmission Event Processing

MCAN uses a Transmit Event FIFO to support the handling of transmission events. After a message is transmitted on the CAN bus, its message ID and timestamp are stored in a transmit event FIFO element. To associate a transmission event with the respective transmit event FIFO entry, the message marker from the transmitted transmit buffer is copied into the transmit event FIFO element.

The transmit event FIFO can be configured with up to 32 elements. For details, refer to the section "[Transmit Event FIFO Element](#)".

The purpose of the transmit event FIFO is to decouple the processing of transmission status information from the processing of transmission data. This allows transmit buffers to store only the message content, while transmission status is independently tracked in the FIFO. This approach offers clear advantages—especially when working with dynamically managed transmission queues. After a message is successfully transmitted, its corresponding transmit buffer can immediately be reused for a new message.

When MCAN\_IR.TEFF indicates that the transmit event FIFO is full, no further elements are written to the transmit event FIFO until at least one element has been read and the transmit event FIFO get index has been incremented. If a transmit event occurs when the transmit event FIFO is full, the event is discarded and the interrupt flag MCAN\_IR.TEFL is set.

To prevent the transmit event FIFO from overflowing, the transmit event FIFO watermark can be used. When the transmit event FIFO fill count reaches the transmit event FIFO watermark configured by TXEFC.EFWM, the interrupt flag MCAN\_IR.TEFW is set.

When reading data from the transmit event FIFO, the transmit event FIFO get index TXEFS.EFGI must be multiplied by 2 (the transmit event FIFO element size is two words), then multiplied by 4, and then added to the transmit event FIFO start address TXEFC.EFSA to get the address where the target data is located.

### 37.3.8 FIFO Confirmation Processing

The acquisition index of receive FIFO0, receive FIFO1 and transmit event FIFO is controlled by writing to the corresponding FIFO confirmation index register, see "[MCAN Receive FIFO0 Confirmation Register \(MCAN\\_RXF0A\)](#)", "[MCAN Receive FIFO1 Confirmation Register \(MCAN\\_RXF1A\)](#)" and "[MCAN Transmit Event FIFO Confirmation Register \(MCAN\\_TXEFA\)](#)". A write operation to the FIFO acknowledgement index sets

the FIFO get index to the FIFO acknowledgement index plus 1, which in turn updates the FIFO fill level. There are two use cases:

1. If only one element is read from the FIFO (the element pointed to by the get index), the get index value should be written to the FIFO acknowledge index register.
2. If a sequence of elements has been read from the FIFO, the FIFO get index can be updated simply by writing the index value of the last element to the FIFO acknowledge index register at the end of the sequence read.

Since the CPU has free access to the MCAN's message RAM, special care needs to be taken when reading FIFO elements in arbitrary order (regardless of the fetch index), especially when reading high priority messages from one of the two receive FIFOs. In this case, the FIFO acknowledge index register should not be written, otherwise the fetch index will point to the wrong location and the FIFO fill level will be changed, and some older FIFO elements may be lost.

**Note**

The application must ensure that the value written to the FIFO confirmation index register is correct; the MCAN does not check whether the value is correct.

### 37.3.9 Message RAM

#### 37.3.9.1 Message RAM Configuration

The width of the message RAM is 32 bits. The MCAN module can allocate up to 1024 words in the message RAM, as shown in the figure below. In actual applications, it is not required to configure all parts, and there is no restriction on the order between the parts.

Figure 37-12 Message RAM Configuration

When the MCAN accesses the message RAM, it needs to address it according to 32-bit aligned addresses instead of byte-aligned addresses. The configurable starting address is a 32-bit word address, that is, only 15 to 2 bits of the address are evaluated, and the two least significant bits are ignored.

The message RAM has ECC check (Error Checking and Correcting). The ECC check is a one-correction-two-check code, that is, it can correct 1-bit errors and check 2-bit errors. ECC check has an error injection function. Based on the settings of the error injection enable register MCANRAM\_EIEN and the error injection bit enable registers MCANRAM\_EIBIT0/ MCANRAM\_EIBIT1, the hardware circuitry will invert the data read from RAM bit by bit to achieve error injection. By setting the error injection bit enable registers MCANRAM\_EIBIT0/MCANRAM\_EIBIT1, 1-bit or multi-bit errors can be induced. Since ECC checking is a single error correction and double error detection code, errors exceeding 2-bit may not be detected. The message RAM check error address register (MCANRAM\_ECCERRADDR) records the access address (offset address relative to the message RAM base address) when a 1-bit or 2-bit ECC error occurs in the message RAM.

**Note**

MCAN does not check whether there are errors in the configuration of the message RAM, so you must be careful when configuring the starting addresses of the different parts and the number of elements in each part to avoid data intrusion or loss.

37.3.9.2 Receive Buffers and FIFO Elements

Up to 64 receive buffers and 2 receive FIFOs can be configured in the message RAM. Each receive FIFO can be configured to store up to 64 messages. The structure of the receive buffer and receive FIFO elements and their description are shown in the following table. The element size can be configured via register MCAN\_RXESC. The data field of a CAN FD message can be up to 64 bytes.

Table 37-9 Receive Buffers and FIFO Elements

### 37.3.9.3 Transmit Buffer Elements

The transmit buffer can be configured as a dedicated transmit buffer and a transmit FIFO (or queue). If the transmit buffer is shared by a dedicated transmit buffer and a transmit FIFO (or queue), the dedicated transmit buffer is at the beginning of the transmit buffer, followed by the transmit FIFO (or queue). The transmit processing unit evaluates the transmit buffer configurations MCAN\_TXBC.TFQS and MCAN\_TXBC.NDTB to distinguish between the dedicated transmit buffer and the transmit FIFO (queue). The structure of the transmit buffer element and its related description are shown in the following table. The element size can be configured through the register MCAN\_TXESC, and the data field of the CAN FD message can be up to 64 bytes.

**Table 37-11 Transmit Buffer Elements**

### 37.3.9.4 Transmit Event FIFO Elements

Each element stores information about the message that has been sent. By reading the Transmit Event FIFO, the host CPU obtains this information in the order in which the messages were sent. The status information about the Transmit Event FIFO can be obtained from the register MCAN\_TXEFS. The structure of the Transmit Event FIFO elements and related descriptions are shown in the following table.

- E1A: When MCAN\_CCCR.WMM=0, E1A.TXTS[15:0] stores the 16-bit timestamp generated by the internal timestamp logic of the MCAN.
- E1B: When the 16-bit wide message marker is enabled (MCAN\_CCCR.WMM=1), E1B.MM[15:8] is the upper 8 bits of the wide message marker.

Copied to the send event FIFO element to identify the send message status.                                                                                                                                      |

### 37.3.9.5 Standard Message ID Filter Element

Up to 128 filter elements can be configured for 11-bit standard IDs (each element is 1 word in size). The address of the filter element is the filter element index (0-127) multiplied by 4 (in bytes), added to the base address MCAN\_SIDFC.FLSSA. The structure of the standard message ID element and its related description are shown in the table below.

**Table 37-15 Standard Message ID Filter Element**

|           | SFID2[10:9] | Determines whether the received message is stored in the receive buffer or processed as message A, B, or C in the debug message sequence. <ul style="list-style-type: none"> <li>● 0b00: store the message into the receive buffer</li> <li>● 0b01: Debug message A</li> <li>● 0b10: Debug message B</li> <li>● 0b11: Debug message C</li> </ul> |
|           | SFID2[5:0]  | Defines the offset (buffer index) from the receive buffer where the matching message is stored to the starting address RXBC.RBSA.                                                                                                                                                                                                                |

### 37.3.9.6 Extended Message ID Filter Element

Up to 64 filter elements (each element is 2 words in size) can be configured for a 29-bit extended ID. When accessing an extended message ID filter element, its address is the filter element index (0 to 63) multiplied by 2, then multiplied by 4 (converted to bytes), and then added to the starting address MCAN\_XIDFC.FLESA. The structure of the extended message ID element and its related description are shown in the following table.

**Table 37-17 Extended Message ID Filter Element**

| Bit | 31   | 30 | 29   | 28    | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |

### 37.4.1 Register List

- MCAN1 base address: 0x4002B000
- MCAN2 base address: 0x4002B400

Table 37-19 Controller Area Network (MCAN) Register Offset

| Offset | Register   | Description                                    | Width |
|--------|------------|------------------------------------------------|-------|
| 0x04   | MCAN_ENDN  | MCAN Byte Order Register                       | 32    |
| 0x0C   | MCAN_DBTP  | MCAN Data Bit Time and Prescaler Register      | 32    |
| 0x10   | MCAN_TEST  | MCAN Test Register                             | 32    |
| 0x14   | MCAN_RWD   | MCAN RAM Watchdog Register                     | 32    |
| 0x18   | MCAN_CCCR  | MCAN CC Control Register                       | 32    |
| 0x1C   | MCAN_NBTP  | MCAN Nominal Bit Time and Prescaler Register   | 32    |
| 0x20   | MCAN_TSCC  | MCAN Timestamp Counter Configuration Register  | 32    |
| 0x24   | MCAN_TSCV  | MCAN Timestamp Counter Value Register          | 32    |
| 0x28   | MCAN_TOCC  | MCAN Timeout Counter Configuration Register    | 32    |
| 0x2C   | MCAN_TOCV  | MCAN Timeout Counter Value Register            | 32    |
| 0x40   | MCAN_ECR   | MCAN Error Counter Register                    | 32    |
| 0x44   | MCAN_PSR   | MCAN Protocol Status Register                  | 32    |
| 0x48   | MCAN_TDCR  | MCAN Transmitter Delay Compensation Register   | 32    |
| 0x50   | MCAN_IR    | MCAN Interrupt Register                        | 32    |
| 0x54   | MCAN_IE    | MCAN Interrupt Enable Register                 | 32    |
| 0x58   | MCAN_ILS   | MCAN Interrupt Line Selection Register         | 32    |
| 0x5C   | MCAN_ILE   | MCAN Interrupt Line Enable Register            | 32    |
| 0x80   | MCAN_GFC   | MCAN Global Filter Configuration Register      | 32    |
| 0x84   | MCAN_SIDFC | MCAN Standard ID Filter Configuration Register | 32    |
| 0x88   | MCAN_XIDFC | MCAN Extended ID Filter Configuration Register | 32    |
| 0x90   | MCAN_XIDAM | MCAN Extended ID and Mask Register             | 32    |
| 0x94   | MCAN_HPMS  | MCAN High Priority Message Status Register     | 32    |
| 0x98   | MCAN_NDAT1 | MCAN New Data 1 Register                       | 32    |

| Offset | Register    | Description                                                       | Width |
|--------|-------------|-------------------------------------------------------------------|-------|
| 0x9C   | MCAN_NDAT2  | MCAN New Data 2 Register                                          | 32    |
| 0xA0   | MCAN_RXF0C  | MCAN Receive FIFO0 Configuration Register                         | 32    |
| 0xA4   | MCAN_RXF0S  | MCAN Receive FIFO0 Status Register                                | 32    |
| 0xA8   | MCAN_RXF0A  | MCAN Receive FIFO0 Acknowledge Register                           | 32    |
| 0xAC   | MCAN_RXBC   | MCAN Receive Buffer Configuration Register                        | 32    |
| 0xB0   | MCAN_RXF1C  | MCAN Receive FIFO1 Configuration Register                         | 32    |
| 0xB4   | MCAN_RXF1S  | MCAN Receive FIFO1 Status Register                                | 32    |
| 0xB8   | MCAN_RXF1A  | MCAN Receive FIFO1 Acknowledge Register                           | 32    |
| 0xBC   | MCAN_RXESC  | MCAN Receive Buffer and FIFO Element Size Configuration Registers | 32    |
| 0xC0   | MCAN_TXBC   | MCAN Transmit Buffer Configuration Register                       | 32    |
| 0xC4   | MCAN_TXFQS  | MCAN Transmit FIFO/Queue Status Register                          | 32    |
| 0xC8   | MCAN_TXESC  | MCAN Transmit Buffer Element Size Configuration Register          | 32    |
| 0xCC   | MCAN_TXBRP  | MCAN Transmit Buffer Request Pending Register                     | 32    |
| 0xD0   | MCAN_TXBAR  | MCAN Transmit Buffer Add Request Register                         | 32    |
| 0xD4   | MCAN_TXBCR  | MCAN Transmit Buffer Cancel Request Register                      | 32    |
| 0xD8   | MCAN_TXBTO  | MCAN Transmit Buffer Transmit Occurred Register                   | 32    |
| 0xDC   | MCAN_TXBCF  | MCAN Transmit Buffer Cancel Completed Register                    | 32    |
| 0xE0   | MCAN_TXBTIE | MCAN Transmit Buffer Transmit Interrupt Enable Register           | 32    |
| 0xE4   | MCAN_TXBCIE | MCAN Transmit Buffer Cancel Completed Interrupt Enable Register   | 32    |
| 0xF0   | MCAN_TXEFC  | MCAN Transmit Event FIFO Configuration Register                   | 32    |
| 0xF4   | MCAN_TXEFS  | MCAN Transmit Event FIFO Status Register                          | 32    |
| 0xF8   | MCAN_TXEFA  | MCAN Transmit Event FIFO Acknowledge Register                     | 32    |

MCANRAM ECC base address: 0x4002D000

Table 37-20 MCANRAM register offset

| Offset | Register                           | Description                                            | Width |
|--------|------------------------------------|--------------------------------------------------------|-------|
| 0x00   | <a href="#">MCANRAM_CKCR</a>       | MCAN Message RAM Check Control Register                | 32    |
| 0x04   | <a href="#">MCANRAM_CKSR</a>       | MCAN Message RAM Check Status Register                 | 32    |
| 0x08   | <a href="#">MCANRAM_EIEN</a>       | MCAN Message RAM Error Injection Enable Register       | 32    |
| 0x0C   | <a href="#">MCANRAM_EIBIT0</a>     | MCAN Message RAM Error Injection Bit Enable Register 0 | 32    |
| 0x10   | <a href="#">MCANRAM_EIBIT1</a>     | MCAN Message RAM Error Injection Bit Enable Register 1 | 32    |
| 0x14   | <a href="#">MCANRAM_ECCERRADDR</a> | MCAN Message RAM Check Error Address Register          | 32    |

37.4.2 MCAN Byte Order Register (MCAN\_ENDN)

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|

| Bit  | Name | Function              | Description                  | Access |
|------|------|-----------------------|------------------------------|--------|
| 31:0 | ETV  | Byte order test value | The test value is 0x87654321 | RO     |

### 37.4.3 MCAN Data Bit Time and Prescaler Register (MCAN\_DBTP)

Write access to this register is possible only when both the MCAN\_CCCR.CCE and MCAN\_CCCR.INIT bits are set. The programmable range for the CAN bit time is from 4 to 49 time quanta(tq). The programmable range for the CAN time quanta is from 1 to 32 MCAN communication clock periods (Minimum time quantum, mtq).  $tq = (DBRP + 1) \cdot mtq$ .  $tq = (DBRP + 1) \cdot mtq$ .

DTSEG1 is the sum of Prop\_Seg and Phase\_Seg1. DTSEG2 is Phase\_Seg2.

Therefore, the length of the bit time is (programmed value) [DTSEG1 + DTSEG2 + 3] tq or (functional value) [Sync\_Seg + Prop\_Seg + Phase\_Seg1 + Phase\_Seg2] tq.

The information processing time (IPT) is zero, which means that the next bit of data is available on the first clock edge after the sampling point.

| Offset | Bit Position |    |    |    |    |    |    |    |     |          |      |    |    |    |          |        |    |    |    |        |     |    |   |      |   |     |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|-----|----------|------|----|----|----|----------|--------|----|----|----|--------|-----|----|---|------|---|-----|---|---|---|---|---|---|

| 12:8  | DTSEG1   | Data Time Before Sample Point       | Active setting: 0-31. The actual value used by hardware is the programmed value plus 1.                                                                                                                                                                                                            | RWA    |
| 7:4   | DTSEG2   | Data Time After Sample Point        | Active setting: 1-15. The actual value used by hardware is the programmed value plus 1.                                                                                                                                                                                                            | RWA    |
| 3:0   | DSJW     | Data (Re)synchronization Jump Width | Active setting: 0-15. The actual value used by hardware is the programmed value plus 1.                                                                                                                                                                                                            | RWA    |

**Note**

1. When the MCAN communication clock is 8 MHz, the reset value 0x00000A33 configures the MCAN data phase bit rate to 500 kbps.
2. The CAN FD data phase bit rate configured via DBTP must not be lower than the arbitration phase bit rate configured via NBTP.

### 37.4.4 MCAN Test Register (MCAN\_TEST)

Only when the MCAN\_CCCR.TEST bit is set to 1 can write access to the test register be enabled. When the MCAN\_CCCR.TEST bit is cleared to 0, all test register functions revert to their reset values.

Loopback mode and software control of the MCAN\_TX pin are considered hardware test modes. If the TX setting is configured to a value other than 0b00, it may interfere with message transmission on the CAN bus.

| Offset | Bit Position                                                                               |    |    |    |    |    |    |    |    |    |      |       |    |    |    |          |      |       |    |    |    |    |     |   |      |          |   |   |   |   |   |   |

### 37.4.5 MCAN RAM Watchdog Register (MCAN\_RWD)

The RAM watchdog monitors the READY signal output of the message RAM. When the message RAM is accessed, the message RAM watchdog counter is started, and the starting value of the counter is configured by the MCAN\_RWD.WDC bit.

When the message RAM indicates that the access is successfully completed by activating its READY signal output, the counter is reloaded with the value of MCAN\_RWD.WDC. If the message RAM does not respond before the counter decrements to 0, the counter stops counting and sets the interrupt flag MCAN\_IR.WDI to 1. The RAM watchdog counter is counted by the MCAN control logic clock.

Therefore, before resetting the INIT value, please confirm that the previous setting value has been written.         </div>                                               | RW     |

### 37.4.7 MCAN Nominal Bit Time and Prescaler Register (MCAN\_NBTP)

This register can be written only when both the MCAN\_CCCR.CCE and MCAN\_CCR.INIT bits are set. The CAN nominal bit time is programmable from 4 to 385 time slices (Time quanta, tq). The CAN time slice is programmable from 1 to 512 MCAN communication clock periods (Minimum time quantum, mtq).  
 $tq = (NBRP + 1) mtq$ .

NTSEG1 is the sum of Prop\_Seg and Phase\_Seg1. NTSEG2 is Phase\_Seg2.

Therefore, the length of the bit time is (programmed value) [NTSEG1 + NTSEG2 + 3] tq or (functional value) [Sync\_Seg + Prop\_Seg + Phase\_Seg1 + Phase\_Seg2] tq.

The information processing time (IPT) is zero, which means that the next bit of data is available on the first clock edge after the sample point.

| Offset | Bit Position |    |    |    |    |    |    |    |      |    |    |    |    |    |    |    |        |    |    |    |    |    |   |   |          |        |   |   |   |   |   |   |  |

#### Note

When the MCAN clock is 8MHz, a reset value of 0x06000A03 will configure the MCAN bit rate to 500kbps.

### 37.4.8 MCAN Timestamp Counter Configuration Register (MCAN\_TSCC)

This register is used to configure the internal 16-bit timestamp counter. For an introduction to internal timestamp processing, see "[Timestamp Generation](#)".

| 15:0  | TSC      | Timestamp counter | <p>The internal timestamp counter value captured when a SOF (Start Of Frame) is received or sent. When MCAN_TSCC.TSS=0b01, the timestamp counter increments by 1 to 16 times the CAN bit time, the specific multiple is determined by the setting value of MCAN_TSCC.TCP. When the count wraps around, the interrupt flag MCAN_IR.TSW will be set to 1. Write operations will clear the counter.</p> <div>  <b>Note</b> <ul style="list-style-type: none"> <li>● "Wraparound" means that the value of the timestamp counter changes from non-zero to zero, not due to a write operation of MCAN_TSCV.</li> <li>● When accessing bytes, writing any byte of this register will cause the timestamp register to be cleared.</li> </ul> </div> | RWC    |

### 37.4.10 MCAN Timeout Counter Configuration Register (MCAN\_TOCC)

For an introduction to the timeout counter, see "[Timeout Counter](#)".

|-----|------|-----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 2:0 | LEC  | Last error code |  <b>Note</b> <ol style="list-style-type: none"> <li>1. When a CAN FD frame with the BRS flag set has reached the Data phase, the next CAN event (error or active frame) will be shown in the DLEC instead of the LEC. An error with fixed stuff bits in the CAN FD CRC sequence will be shown as a Form Error instead of a Stuff Error.</li> <li>2. The Bus_Off recovery sequence (see ISO11898-1:2015) cannot be shortened by setting or clearing MCAN_CCCR.INIT. If the device enters the Bus_Off state, it will automatically set MCAN_CCCR.INIT, stopping all bus activity. Once MCAN_CCCR.INIT is cleared by the CPU, the device will wait for 129 bus idles (129*11 consecutive recessive bits) before resuming normal operation. At the end of the Bus_Off recovery sequence, the error management counter will be reset. During the waiting period after clearing MCAN_CCCR.INIT, each time an 11-bit recessive sequence is detected, a Bit0 error code is written to MCAN_PSR.LEC, allowing the CPU to check at any time whether the CAN bus is in a dominant state or is continuously disturbed, and monitor the Bus_Off recovery sequence. MCAN_ECR.REC is used to count these sequences.</li> <li>3. For byte operations, reading byte 0 of the register will set this bit to 0b111, and reading bytes 3/2/1 has no effect.</li> </ol> | RS     |

| 14:8  | TDCO     | Transmit delay compensation SSP offset          | The offset value refers to the distance between the delay measured from the MCAN_TX pin to the MCAN_RX pin and the second sampling point (SSP). The active setting value is 0-127mtq                                                                                                                     | RWA    |
| 7     | Reserved | Reserved                                        | -                                                                                                                                                                                                                                                                                                        | -      |
| 6:0   | TDCF     | Transmit delay-compensation filter window width | Defines the minimum value of the SSP position. For the measurement of transmit delay, the dominant edge on the MCAN_RX pin that would cause the SSP position to advance will be ignored. This function is enabled when the TDCF setting value is greater than TDCO. The active setting value is 0-127mtq | RWA    |

### 37.4.15 MCAN Interrupt Register (MCAN\_IR)

When one of the conditions in the following list is detected, the corresponding flag bit will be set. The flag bit remains set until the host clears it. **All flag bits write 1 to clear flag, write 0 has no effect.** A hard reset will clear the register. Whether an interrupt is generated is controlled by register MCAN\_IE; which interrupt line generates the interrupt is controlled by register MCAN\_ILS.

| Offset | Bit Position |     |     |     |     |    |    |    |     |     |     |     |     |      |     |      |      |      |      |     |     |    |     |      |      |      |      |      |      |      |      |    |

In the case of a failure in the send processing unit access, the MCAN is switched to the restricted working mode (see "<a href="#">Restricted Working Mode</a>" for details). To exit restricted operating mode, the host CPU must reset MCAN_CCCR.ASM.</li> </ul> | RW     |

### 37.4.16 MCAN Interrupt Enable Register (MCAN\_IE)

The settings in the interrupt enable register determine which state changes in the interrupt register (MCAN\_IR) will be indicated on the interrupt line.

### 37.4.17 MCAN Interrupt Line Selection Register (MCAN\_ILS)

The interrupt line select register assigns the interrupt generated by a specific interrupt flag in the interrupt register (MCAN\_IR) to one of the two interrupt lines. To generate an interrupt, the corresponding interrupt lines must be enabled via MCAN\_ILE.EINT0 and MCAN\_ILE.EINT1.

| Offset | Bit Position |      |      |      |      |     |     |     |      |      |      |      |      |       |      |       |       |       |       |      |      |     |      |       |       |       |       |       |       |       |       |    |

| 28:0  | EIDM     | Extended ID mask | For extended frame reception filtering, EIDM is ANDed with the ID of the received frame. Used to mask the 29-bit ID in SAE J1939. The reset value of all bits is set to 1 and the mask has no effect. | RWA    |

### 37.4.23 MCAN High Priority Message Status Register (MCAN\_HPMS)

A message ID filter element configured to generate a priority event updates this register each time it is matched. This can be used to monitor the status of received high priority messages and provide quick access to these messages.

| 5:0  | F1AI     | Receive FIFO1 acknowledge index | After the host reads a message or sequence of messages from the receive FIFO1, it must write the buffer index of the last element read from the receive FIFO1 to F1AI. This operation sets the receive FIFO1 get index MCAN_RXF1S.F1GI to F1AI plus 1 and updates the FIFO1 fill level MCAN_RXF1S.F1FL | RW     |

### 37.4.33 MCAN Receive Buffer and FIFO Element Size Configuration Registers (MCAN\_RXESC)

Configure the receive buffer and the number of data bytes for the receive FIFO elements. Data fields larger than 8 bytes are only applicable in CAN FD mode.

### 37.4.34 MCAN Transmit Buffer Configuration Register (MCAN\_TXBC)

Write access to this register is possible only when both the CCE bit and the INIT bit of the MCAN\_CCCR register are set to 1.

| Offset | Bit Position |      |      |    |    |    |    |          |      |    |    |    |    |            |    |    |    |    |    |    |    |    |   |   |   |   |   |   |          |   |   |   |

#### Note

The sum of TFQS and NDTB shall not be greater than 32. MCAN does not monitor this configuration error. The transmit buffer portion of the message RAM starts with a dedicated transmit buffer.

### 37.4.35 MCAN Transmit FIFO/Queue Status Register (MCAN\_TXFQS)

The status of the transmit FIFO or queue is related to the pending transmit request in register MCAN\_TXBRP. Therefore, the effect of adding or canceling a request may be delayed due to a transmit scan that is running (TXBRP has not yet been updated).

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |      |       |    |    |    |          |    |    |    |      |    |    |   |          |   |      |   |   |   |   |   |   |  |

| 20:16 | TFQPI    | Transmit FIFO/queue put index | The put index pointer of the transmit FIFO or queue, the active range is 0-31                                                                                                                                | RO     |
| 15:13 | Reserved | Reserved                      | -                                                                                                                                                                                                            | -      |
| 12:8  | TFGI     | Transmit FIFO get index       | The read index pointer of the transmit FIFO, the active range is 0-31. If it has been configured as the transmit queue mode (MCAN_TXBC.TFQM=1), the read value of this bit is 0                              | RO     |
| 7:6   | Reserved | Reserved                      | -                                                                                                                                                                                                            | -      |
| 5:0   | TFFL     | Transmit FIFO idle level      | The number of consecutive idle transmit FIFO elements starting from TFGI, the active range is 0-32. If it has been configured as the transmit queue mode (MCAN_TXBC.TFQM=1), the read value of this bit is 0 | RO     |

#### Note

In the case where a dedicated transmit buffer is configured in combination with a transmit FIFO or a transmit queue, the put index and get index refer to the transmit buffer number starting from the first dedicated transmit buffer.

For example: For a combined configuration with 12 dedicated transmit buffers and 20 transmit FIFO buffers, put index 15 to point to the 4th buffer of the transmit FIFO.

### 37.4.36 MCAN Transmit Buffer Element Size Configuration Register (MCAN\_TXESC)

Configure the number of data bytes for a transmit buffer element. Data fields larger than 8 bytes are only applicable in CAN FD mode.

|------|------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 31:0 | TRPn<br>(n=31-0) | <p>Transmit request pending flag</p> <p>Corresponding to the transmit request pending bits of transmit buffers 31-0:</p> <ul style="list-style-type: none"> <li>0b0: No transmit request pending</li> <li>0b1: Transmit request pending</li> </ul> <p>These bits are set by register MCAN_TXBAR; reset after the requested transmit is completed or the requested transmit is canceled by register MCAN_TXBCR.</p> <p>The TXBRP bit corresponding to the transmit buffer configured by MCAN_TXBC is set. When the TXBRP bit is set, a transmit scan (see "<a href="#">Transmission Processing</a>") is started to check the highest priority pending transmit request (i.e. the transmit buffer with the smallest message ID).</p> <p>Canceling a transmit request resets the corresponding TXBRP bit. If the transmit has already started when the request is canceled, the TXBRP bit will be reset at the end of the transmission regardless of whether the transmit is successful or not. After the TXBRP bit is reset, the corresponding cancel request bit will also be reset immediately.</p> <p>After requesting cancellation, the following situations indicate cancellation completion through register MCAN_TXBCF:</p> <ul style="list-style-type: none"> <li>After successful transmission and corresponding MCAN_TXBTO bit is set</li> <li>Transmission has not started at the time of cancellation</li> <li>Transmission is aborted due to arbitration failure</li> <li>Error occurs during frame transmission</li> </ul> <p>In DAR mode, all transmissions are automatically canceled after failure. For all failed transmissions, the corresponding MCAN_TXBCF bit is set.</p> <div>  <b>Note</b><br/> Each bit corresponds to a buffer.<br/><br/> TXBRP bits set during the transmission scan are ignored during this transmission scan. During this period, if cancellation of these transmissions is requested, the transmission is immediately canceled and the corresponding TXBRP bits are reset. </div> | RO     |

| 1:0  | ECCMOD   | ECC check enable bit of message RAM | <ul style="list-style-type: none"> <li>● 0b00: Disable ECC check function.</li> <li>● 0b01: <ul style="list-style-type: none"> <li>▶ If a single-bit error occurs, ECC corrects it without generating a single-bit error flag or interrupt.</li> <li>▶ If a double-bit error occurs, ECC detects the error, sets the double-bit error flag, and generates an interrupt.</li> </ul> </li> <li>● 0b10: <ul style="list-style-type: none"> <li>▶ If a single-bit error occurs, ECC corrects the error, sets the single-bit error flag, and no interrupt is generated.</li> <li>▶ If a double-bit error occurs, ECC detects the error, sets the double-bit error flag, and generates an interrupt.</li> </ul> </li> <li>● 0b11: <ul style="list-style-type: none"> <li>▶ If a single-bit error occurs, ECC corrects the error, sets the single-bit error flag, and generates an interrupt.</li> <li>▶ If a double-bit error occurs, ECC detects the error, sets the double-bit error flag, and generates an interrupt.</li> </ul> </li> </ul> | RW     |

**Note**

1. When using the ECC function of the message RAM, you must configure ECCMOD before reading or writing accesses to the message RAM, and then initialize the used message RAM space in units of words.
2. When ECCMOD is 0b10 or 0b11, if MCAN1/MCAN2 generates a 1-bit error when accessing the message RAM, MCAN\_IR.BEC of MCAN1/MCAN2 is set, and if the corresponding interrupt is enabled, MCAN1/MCAN2 generates an interrupt.
3. When ECCMOD is 0b01, 0b10 or 0b11, if MCAN1/MCAN2 generates a 2-bit error when accessing the message RAM, MCAN\_IR.BEU of MCAN1/MCAN2 is set, and if the corresponding interrupt is enabled, MCAN1/MCAN2 generates an interrupt.

| 11:0  | ECCERRADDR | Check Error Address | Records the access address when a 1-bit or 2-bit ECC error occurs in the message RAM (the offset address relative to the message RAM base address) | RO     |

## 37.5 Precautions

### 37.5.1 CAN Bus Anti-Interference Measures

CAN bus is widely used in the automotive, industrial control and other industries. If the electromagnetic environment at the CAN application site is relatively bad, with factors such as circuit imbalance, spatial electromagnetic field, and power grid incoming lines, the CAN bus will generate a lot of communication noise due to radiation and conduction interference, resulting in an increase in bus error frames, frequent retransmissions, and the failure of correct data to arrive in time. It may also lead to undefined errors in the CAN protocol, bus anomalies and other unexpected situations, seriously affecting the quality of data communication. Therefore, in practical applications, efforts should be made to eliminate noise interference and ensure stable operation of the CAN bus network.

The following are several commonly used CAN bus anti-interference measures (including but not limited to) :

1. Add electrical isolation for the CAN bus interface
2. Common signal ground for transceivers
3. Use shielded twisted pair cables and properly ground them
4. Increase the degree of twisting of CAN transmission lines
5. Add signal protector
6. Improve network topology
7. Anti-interference mechanisms at the application layer software

### 37.5.2 CAN Controller Noise Constraints

In the CAN bus network, it should be ensured that the bit time of the communication meets the requirements of the standard protocol. If the noise interference that does not meet the bit time width is introduced, it may cause the abnormal operation of the MCAN controller.

## 38 Ethernet MAC Controller (ETHMAC)

### 38.1 Introduction

Ethernet MAC controller (ETHMAC) is used to send and receive data in Ethernet network according to IEEE802.3-2002 standard, and it has many application fields, such as switches and network interface cards. The MAC controller supports two industrial standard interfaces connected with external physical layer (PHY) : Media Independent Interface (MII) (defined in IEEE802.3 specification) and Simplified Media Independent Interface (RMII).

Mainly follow the following protocol specifications:

- IEEE802.3-2002, used for Ethernet MAC
- IEEE1588-2008 standard, used to specify network clock synchronization
- AMBA2.0, for AHB master/slave ports
- RMII interface specification

### 38.2 Features

#### 38.2.1 ETH\_MAC Features

The basic functional features of the ETH\_MAC module are as follows:

- Support for external PHY interface to achieve 10/100Mbps data transfer rate
- Support for MII or RMII interface to communicate with external fast Ethernet PHY
- Provide separate transmit, receive, and control interfaces for applications
- Use SMI interface to configure and manage up to 32 PHY devices
- Support for detecting remote wakeup frames and AMD Magic Packet™ frames
- Support for LoopBack mode with internal loopback via MII
- Support for full-duplex and half-duplex operations:
  - ▶ Support for CSMA/CD protocol suitable for half-duplex operation
  - ▶ Support for backpressure flow control suitable for half-duplex operation
  - ▶ Support for IEEE802.3x flow control suitable for full-duplex operation
  - ▶ In full-duplex operation, the received pause control frame can be forwarded to the application

#### Note

The "application" referred to in this section means that the MAC transmits the received frame to the system memory through RxDMA for use by the upper-layer network layer and transport layer; or it transmits the data from the upper-layer network layer and transport layer from the system controller to the MAC through TxDMA. The upper-layer network layer and transport layer are called applications.

- ▶ In full-duplex operation, if the flow control input signal disappears, a zero-time pause frame is sent automatically
- Ethernet frame processing:
  - ▶ When receiving an Ethernet frame, automatically remove the PAD and FCS fields of frames with length fields less than 1536
  - ▶ When receiving an Ethernet frame, automatically remove the FCS field of the type frame
  - ▶ When receiving an Ethernet frame, automatically perform CRC calculation of the received frame

- ▶ When sending an Ethernet frame, insert and replace the SA
- ▶ When sending an Ethernet frame, insert and replace the CRC
- ▶ When sending an Ethernet frame, insert, replace, and delete the VLAN frame identifier
- ▶ When sending an Ethernet frame, automatically generate PAD filling for frames smaller than 60 bytes
- ▶ When sending an Ethernet frame, automatically retransmit conflict frames
- ▶ When sending an Ethernet frame, support programmable frame intervals (40-96 bit times, with 8 as the step length)
- ▶ When receiving or sending an Ethernet frame, the frame length can be programmed, supporting giant frames up to 16KB
- Ethernet frame address filtering:
  - ▶ Support up to five 48-bit perfect (DA) address filters, performing mask operations on each byte
  - ▶ Support up to four 48-bit perfect (SA) address filters, performing mask operations on each byte
  - ▶ Support for 64-bit Hash filter, suitable for unicast and multicast target address filtering
  - ▶ Can transmit all multicast address frames
  - ▶ Support for mixed mode, can transmit all frames, no need to filter for network monitoring
  - ▶ A status report is attached when transmitting all incoming data packets (each time filtered)
- VLAN identifier filtering:
  - ▶ Supports a VLAN tag filtering set
  - ▶ Support for 12-bit/16-bit VLAN tag selection
  - ▶ Support for VLAN mark Hash filter
- LAY3 IP message address filtering:
  - ▶ Support for a set of LAY3 IP message address filters, performing mask operations on each byte
  - ▶ Support for address filtering selection of IPv4 messages and IPv6 messages
- LAY4 TCP/UDP message port filtering:
  - ▶ Support for a set of LAY4 TCP/UDP message port filters
- Remote wake-up frame filtering mode
  - ▶ Support for four sets of remote wakeup frame filters, controlling four sets of mask operations
- COE engine:
  - ▶ When receiving frames, you can choose to discard frames without TCP/UDP fields
  - ▶ Check the Header Checksum field of the received IPv4 message
  - ▶ Check the Checksum field of the received TCP messages, UDP messages, and ICMP messages
  - ▶ Perform Checksum calculation for the sent IPv4 message and insert the result into the Header Checksum field
  - ▶ Perform Checksum calculation for the sent TCP messages, UDP messages, and ICMP messages, and insert the result into the Checksum field
- Support for MMC counters to perform network statistics
- FIFO processing:
  - ▶ A 2KB transmit FIFO (Tx FIFO) with a programmable threshold and a 2KB receive FIFO (Rx FIFO) with a configurable threshold
  - ▶ Both Rx FIFO and Tx FIFO support store-and-forward mode
  - ▶ Software-controlled Tx FIFO flush

- ▶ In store-and-forward mode, Rx FIFO can choose to filter out all error frames and not forward these error frames to the application
- ▶ Rx FIFO can automatically generate pause control frames or backpressure signals to be sent to the MAC core based on the fill level (configurable threshold)
- ▶ Frames lost or corrupted in the Rx FIFO can be counted
- ▶ When the Rx FIFO stores multiple frames, by inserting a receive status vector into the Rx FIFO after the EOF transfer, the Rx FIFO does not need to store the receive status of these frames

### 38.2.2 ETH\_PTP Features

The basic functional features of the ETH\_PTP module are as follows:

- Support for taking timestamp snapshots of received and transmitted frames and inserting time-stamps
- Support for coarse and fine calibration of system time
- Support for 2 sets of target time settings, interrupts are triggered when the system time is greater than the target time
- Support for 2 sets of PPS outputs, which can be used as event outputs to control the actions of other modules

### 38.2.3 ETH\_DMA Features

The basic functional features of the ETH\_DMA are as follows:

- Support for software setting of the AHB burst type of the AHB Master interface (fixed or undefined burst)
- Support for all AHB burst types in the AHB Slave interface
- The AHB Master interface can choose address-aligned burst transfers
- Support for RxDMA and TxDMA engines to program burst lengths separately to fully utilize the bus
- Support for byte-aligned addressing of the data buffer
- Descriptor features:
  - ▶ Support for two types of descriptor linking methods: ring and chain
  - ▶ The descriptor architecture can transmit large data blocks with almost no CPU intervention
  - ▶ Each descriptor can transmit up to 8KB of data
- Both TxDMA and RxDMA support store-and-forward mode
- Report the comprehensive status of normal operation and transmission errors
- Programmable interrupt options, choose different interrupts according to different application scenarios
- Frame-controlled send/receive complete interrupt
- Use circular scheduling arbitration or fixed priority arbitration between the receive engine and the transmit engine

## 38.3 Functional Description

The Ethernet MAC controller follows the IEEE802.3 international standard for local area networks (LAN), using the CSMA/CD (Carrier Sense Multiple Access with Collision Detection) method as the basic communication method. It includes a MAC802.3 (Media Access Control) controller with MII and RMII interfaces and a dedicated DMA controller.

### 38.3.1 Basic Block Diagram

The figure below is the architecture diagram of the Ethernet MAC controller.

Figure 38-1 Ethernet MAC Controller Architecture Diagram

From the figure, it can be seen that the core part of the Ethernet MAC controller includes the AHB Master interface, AHB Slave interface, Rx FIFO, Tx FIFO, DMA controller, MAC controller, interface control logic, etc. The DMA controller connects the MAC core to the system memory through the AHB master-slave interface.

The AHB Master interface is used for data transfer, and the AHB Slave interface is used for basic register access configuration of the controller.

When transmitting data, first send the data from the system memory to the Tx FIFO for buffering through the DMA controller, then send it to the external PHY through the MII interface or the RMII interface after a series of processing by the MAC controller (COE control, PTP control, MMC control, etc.).

When receiving data, the data received through the MII interface or the RMII interface is sent to the Rx FIFO after a series of processing by the MAC controller (COE control, PTP control, MMC control, etc.), and then transmit the data from the Rx FIFO to the system memory by DMA controller.

### 38.3.2 Interface Description

The Ethernet MAC controller supports MII, RMII, and SMI interface types. Users can choose one of the MII and RMII interfaces according to actual needs for data exchange. The SMI interface exists independently and is used for basic configuration-related data exchange with the PHY.

By setting the IFSEL bit of the interface control register (ETH\_MAC\_IFCONFR), you can choose whether the Ethernet uses the MII interface or the RMII interface. This bit must be set first before configuring other features of ETHMAC.

#### 38.3.2.1 MII Interface

The Medium Independent Interface (MII) defines the interconnection between the MAC sublayer and the PHY at data transfer rates of 10Mbps and 100Mbps. The figure below shows the basic connection diagram of the MII interface.

Figure 38-2 MII Interface Connection Diagram

The following table introduces the functions of each signal in the MII interface.

Table 38-1 MII Interface Signal Description

| Interface Signal Name | Description                                                                                                                                                                                                                                                                                                                                |
|-----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| MII_TX_CLK            | Sends Clock Signal.<br>This signal provides the reference timing for TX data transmission. It is 2.5MHz at a rate of 10Mbps; it is 25MHz at a rate of 100Mbps.                                                                                                                                                                             |
| MII_RX_CLK            | Receive Clock Signal.<br>This signal provides the reference timing for RX data transmission. It is 2.5MHz at a rate of 10Mbps; it is 25MHz at a rate of 100Mbps.                                                                                                                                                                           |
| MII_TX_EN             | Send Enable Signal.<br>This signal indicates that the MAC is currently transmitting data to the MII.                                                                                                                                                                                                                                       |
| MII_TX_ER             | Send Error Signal.                                                                                                                                                                                                                                                                                                                         |
| MII_TXD[3:0]          | Send Data Signal.<br>This signal is a group of four data signals, synchronously driven by the MAC sublayer, and is only active when the MII_TX_EN signal is enable. MII_TXD[0] is the least significant bit, and MII_TXD[3] is the most significant bit. When the MII_TX_EN signal is disabled, transmitting data does not affect the PHY. |

| Interface Signal Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|-----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| MII_RX_DV             | Receive Data Active Signal.<br>This signal indicates that the PHY is currently sending data to the MII. To correctly receive a frame, this signal must cover the frame to be received in the time range, and its start time must not be later than the time when the SFD field appears.                                                                                                                                                                                                                            |
| MII_RX_ER             | Receive Error Signal.<br>This signal must be maintained for one or more transmit clock periods to indicate to the MAC sublayer that an error is detected somewhere in the frame. This error condition must be verified by the RX_DV signal (see <a href="#">Table 38-3 : Signal State Description when Receiving Data</a> ).                                                                                                                                                                                       |
| MII_RXD[3:0]          | Receive Data Signal.<br>This signal is a group of 4 data signals, driven synchronously by the external PHY, and is a active signal only when the MII_RX_DV signal is enable. MII_RXD[0] is the least significant bit, and MII_RXD[3] is the most significant bit. When the MII_RX_DV signal is disabled and the MII_RX_ER signal is enabled, specific MII_RXD[3:0] values are used to transmit specific information from the PHY (see <a href="#">Table 38-3 : Signal State Description when Receiving Data</a> ). |
| MII_CRS               | Carrier Sense Signal.<br>When the transmit or receive medium is not in an idle state, this signal is enabled by the PHY; when both the transmit and receive media are in an idle state, this signal is disabled by the PHY. The PHY must ensure that the MII_CRS signal remains active under conflict conditions. This signal does not need to be synchronized with the TX and RX clocks. This signal is meaningless in full-duplex mode.                                                                          |
| MII_COL               | Conflict Detection Signal.<br>After detecting a conflict on the medium, the PHY must immediately enable the conflict detection signal, and as long as the conflict condition exists, the conflict detection signal must remain active. This signal does not need to be synchronized with the TX and RX clocks. This signal is meaningless in full-duplex mode.                                                                                                                                                     |

The following table introduces the signal encoding states when sending data.

**Table 38-2 Signal State Description When Sending Data**

| MII_TX_EN | MII_TX_ER | MII_TXD[3:0]  | State Description                           |
|-----------|-----------|---------------|---------------------------------------------|
| 0b0       | 0b0       | 0b0000-0b1111 | Normal frame interval, no data transmission |
| 0b0       | 0b1       | 0b0000-0b1111 | Meaningless                                 |
| 0b1       | 0b0       | 0b0000-0b1111 | Normal data transmission                    |
| 0b1       | 0b1       | 0b0000-0b1111 | Error in data transmission                  |

The following table introduces the signal encoding states when receiving data.

**Table 38-3 Signal State Description when Receiving Data**

| MII_RX_DV | MII_RX_ER | MII_RXD[3:0]  | State Description                        |
|-----------|-----------|---------------|------------------------------------------|
| 0b0       | 0b0       | 0b0000-0b1111 | Normal frame interval, no data reception |

| MII_RX_DV | MII_RX_ER | MII_RXD[3:0]  | State Description       |
|-----------|-----------|---------------|-------------------------|
| 0b0       | 0b1       | 0b0000        | Normal frame interval   |
|           |           | 0b0001-0b1101 | Meaningless             |
|           |           | 0b1110        | Error carrier detection |
|           |           | 0b1111        | Meaningless             |
| 0b1       | 0b0       | 0b0000-0b1111 | Normal data reception   |
| 0b1       | 0b1       | 0b0000-0b1111 | Errors in received data |

### 38.3.2.2 RMII Interface

The Reduced Medium Independent Interface (RMII) specification reduces the number of ports between the microcontroller Ethernet MAC controller and the external PHY at 10/100Mbps. The number of ports it uses is reduced from 16 of MII to 7, as shown in the figure below.

Figure 38-3 RMII Interface Connection Diagram

From the connection diagram, the following main differences can be seen between the RMII interface and the MII interface:

1. The transmit clock and receive clock are unified as the reference clock RMII\_REF\_CLK, which must be a 50MHz clock
2. The data lines are reduced from 4 to 2
3. The MII\_COL signal is discarded, and the MII\_RX\_DV and MII\_CRD signals are combined into the RMII\_CRD\_DV signal
4. MII\_TX\_ER and MII\_RX\_ER signals are discarded

### 38.3.2.3 SMI Interface

The SMI interface can implement station management of the PHY through the Ethernet MAC controller. The MAC controller accesses any PHY register through two lines of clock and data. This interface supports access to up to 32 PHYs. The figure below is the connection diagram of the SMI interface.

Figure 38-4 SMI Interface Connection Diagram

The functions of each signal within the SMI are described in the following table.

Table 38-4 SMI Interface Signal Description

| Interface Signal Name | Description                                                                                                                                                                                                                                                                                                  |
|-----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| SMI_MDC               | Periodic clock, providing reference timing for data transmission at a maximum frequency of 2.5MHz. The shortest high level and the shortest low level of MDC must both be 160ns. The minimum period for the MDC signal must be 400ns. In the idle state, the SMI drives the MDC clock signal to a low level. |
| SMI_MDIO              | Data input/output bit stream, used for data information transfer with the PHY device through the MDC clock signal.                                                                                                                                                                                           |

The MAC controller can select one PHY from 32 PHYs, and then select one register from the 32 registers contained in the selected PHY to transmit control data or receive status information. Only one register in one PHY can be addressed at any given time.

The frame format of SMI is shown in the following table, and the following format is followed during data exchange with PHY:

Table 38-5 SMI Frame Format

|       | Detailed description of the SMI frame format |       |           |        |        |      |               |      |
|-------|----------------------------------------------|-------|-----------|--------|--------|------|---------------|------|
|       | Head (32-bit)                                | Start | Operation | PhyAdd | RegAdd | TA   | Data (16-bit) | Idle |
| Read  | 0b1...1                                      | 0b01  | 0b10      | 0bxxxx | 0bxxxx | Z0   | 0bxx...xx     | Z    |
| Write | 0b1...1                                      | 0b01  | 0b01      | 0bxxxx | 0bxxxx | 0b10 | 0bxx...xx     | Z    |

### 38.3.2.4 Ethernet Port Configuration

Based on the above three types of data interfaces, MII, RMII, and SMI, the correspondence between the port function allocation of the Ethernet MAC controller and each type of interface is organized in the following table:

Table 38-6 ETHMAC Port Function Allocation

| ETH Port Name       | Interface Function Signal |
|---------------------|---------------------------|
| ETH_MII_RMII_RXCLK  | MII_RX_CLK/RMII_REF_CLK   |
| ETH_MII_TXCLK       | MII_TX_CLK                |
| ETH_MII_RMII_TXEN   | MII_TX_EN/RMII_TX_EN      |
| ETH_MII_TXER        | MII_TX_ER                 |
| ETH_MII_RMII_TXD1-0 | MII_TXD[0]/RMII_TXD[0]    |
|                     | MII_TXD[1]/RMII_TXD[1]    |
| ETH_MII_TXD3-2      | MII_TXD[2]                |
|                     | MII_TXD[3]                |
| ETH_MII_RMII_RXDV   | MII_RX_DV/RMII_CRS_DV     |
| ETH_MII_RXER        | MII_RX_ER                 |
| ETH_MII_RMII_RXD1-0 | MII_RXD[0]/RMII_RXD[0]    |
|                     | MII_RXD[1]/RMII_RXD[1]    |

| ETH Port Name  | Interface Function Signal |
|----------------|---------------------------|
| ETH_MII_RXD3-2 | MII_RXD[2]                |
|                | MII_RXD[3]                |
| ETH_MII_CRS    | MII_CRS                   |
| ETH_MII_COL    | MII_COL                   |
| ETH_SMI_MDC    | SMI_MDC                   |
| ETH_SMI_MDIO   | SMI_MDIO                  |

### 38.3.3 ETH\_MAC Function

#### 38.3.3.1 ETH\_MAC Function Overview

The MAC sublayer performs the following functions related to data link control steps:

- Data package (transmit and receive)
  - ▶ Frame formation (frame boundary definition, frame synchronization)
  - ▶ Addressing (processing source and destination addresses)
  - ▶ Error detection
- Medium access management
  - ▶ Medium allocation (collision avoidance)
  - ▶ Contention resolution (collision handling)

The MAC sublayer has two main operating modes:

- Half-duplex mode: Stations use the CSMA/CD algorithm to contend for the physical medium
- Full-duplex mode: When the following conditions are met, competition issues do not need to be resolved (the CSMA/CD algorithm is not required) to send and receive data simultaneously:
  - ▶ The physical medium can support synchronous sending and receiving
  - ▶ Exactly 2 stations are connected to the LAN
  - ▶ Both stations are configured for full-duplex operating mode

#### 38.3.3.2 MAC 802.3 Frame Format

MAC data communication can use two frame formats:

- Basic MAC frame structure
- MAC frame format with VLAN tag (an extension of the basic MAC frame format)

The figure below shows the specific structures of the two frame formats.

*Basic MAC Frame Format*

|                      |                                      |                               |                               |                                     |                |             |                                     |
|----------------------|--------------------------------------|-------------------------------|-------------------------------|-------------------------------------|----------------|-------------|-------------------------------------|
| Preamble<br>(7 Byte) | Start Frame<br>Delimiter<br>(1 Byte) | Target<br>Address<br>(6 Byte) | Source<br>Address<br>(6 Byte) | Length/Type<br>LEN/TYPE<br>(2 Byte) | DATA           | Filling PAD | Frame Check<br>Sequence<br>(4 Byte) |
|                      |                                      |                               |                               |                                     | (46~1500 Byte) |             |                                     |

*MAC Frame Format with VLAN Flag***Figure 38-5 MAC Frame Structure**

Except for the frame check sequence (FCS), the Ethernet MAC controller sends each byte in the order of least significant bit first.

CRC calculation includes all bytes of frame data except for the preamble and start frame delimiter fields. The 32-bit CRC generator polynomial for Ethernet frames is 0x04C11DB7, and this polynomial is used for all 32-bit CRC calculations in the Ethernet module, as shown in the following formula:

$$G(x)=x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$$

A frame is defined as an inactive MAC frame by one of the following conditions:

- The frame length does not match the expected value specified by the length/type field. If the length/type field contains a type value, the frame length is considered consistent with this field (no inactive frames)
- The frame length is not an integer multiple of bytes (extra bits)
- The CRC value calculated based on the incoming frame does not match the included FCS

**38.3.3.3 MAC Frame Transmission Action**

TxDMA controls all transactions on the transmit path. The Ethernet frame read from the system memory is sent to the Tx FIFO by TxDMA and then transmitted to the MAC core. At the end of frame transmission, the transmit status is obtained from the MAC core and sent back to TxDMA.

The Ethernet MAC controller is equipped with a 2KB Tx FIFO. The Tx FIFO fill level is indicated to the DMA so that TxDMA can initiate data transfer in the required system memory via the AHB interface. Data from the AHB Master interface is sent to the Tx FIFO.

When SOF is detected, the MAC receives data and begins to send it to the MII. After the application starts sending, the time required to send frame data to the MII is variable, depending on delay factors such as IFG delay, time to send the header/SFD, and any backoff delay in half-duplex mode. After the EOF is transmitted to the MAC core, the core completes the normal transmission and then return the transmission status to the TxDMA. If a normal collision occurs during transmission (in half-duplex mode), the MAC core activeates the transmission status, then accept and discard all subsequent data until the next SOF is received. When a retry request from the MAC is detected (in the status), the same frame should be retransmitted starting from the SOF.

If data is not continuously provided during transmission, the MAC issues an underflow status. During the normal transmission of a frame, if the MAC receives an SOF without obtaining the EOF of the previous frame, it ignores the SOF and treat the new frame as a continuation of the previous frame.

There are two operating modes for delivering data to the MAC core:

- In threshold mode, once the number of bytes in the FIFO exceeds the configured threshold (or the end of the frame is written before exceeding the threshold), the data is ready and forwarded to the MAC core. This threshold can be configured using the TTC bit in ETH\_DMA\_OPRMODR.
- In store-and-forward mode, frames are delivered to the MAC core only after a complete frame is stored in the FIFO. If the size of the Tx FIFO is smaller than the Ethernet frame to be sent, the frame is delivered to the MAC core when the Tx FIFO is nearly full.

The application can empty all contents of the Tx FIFO by setting the FTF bit (ETH\_DMA\_OPRMODR register[20]) to 1. This bit self-clears and initializes the FIFO pointer to the default state. If this bit is set to 1 during frame transmission to the MAC core, the transmission stops, the Tx FIFO is considered empty, an underflow event occurs in the MAC transmitter, and the corresponding status word is forwarded to the TxDMA.

### Basic Protocol Transmission

The MAC controls the transmission of Ethernet frames. It performs the following functions to meet the IEEE802.3/802.3z specifications. Includes:

- Generates the header and SFD
- Generates a Jam signal in half-duplex mode
- Controls Jabber timeout
- Controls traffic (backpressure) in half-duplex mode
- Transmit frame status generation
- Includes IEEE1588-compliant timestamp snapshot logic

When a new frame is requested for transmission, the MAC transmits the header and SFD, followed by the transmit data. The header is defined as 7 bytes of "10101010" pattern, and the SFD is defined as 1 byte of "10101011" pattern.

The collision window is defined as 1 slot (512 bit times for 10/100Mbps Ethernet). Jam signal generation is only applicable in half-duplex mode and not in full-duplex mode. In MII mode, if a collision occurs at any time between the start of frame transmission and the end of the CRC field, the MAC transmits a 32-bit Jam signal of 0x55555555 on the MII to notify all other stations of the collision. If a collision occurs during the header transmission phase, the MAC completes the transmission of the header and SFD, then send the Jam signal.

The MAC core uses a Jabber timer to cut off Ethernet frame transmission when the transmitted bytes exceed 2048 bytes. In half-duplex mode, the MAC uses a deferral mechanism for traffic control (backpressure). When the application requests to stop receiving frames, if transmit flow control is enabled, the MAC transmits a 32-byte Jam signal whenever it detects a received frame. This causes a collision and makes the remote station back off. The application requests flow control by setting the BPA bit in the ETH\_MAC\_FLOCTLR register to 1. If the application requests to send a frame, it is transmitted as scheduled even if the backpressure function is active. If the backpressure function remains active for a long time (more than 16 consecutive collision events), the remote station aborts transmission due to excessive collisions. If the IEEE1588 timestamp function is enabled for a transmitted frame, a snapshot of the system time is captured when the SFD is placed on the transmit MII bus.

## Scheduling Algorithm Implementation

The MAC is responsible for scheduling frame transmission on the MII. The inter-frame gap between two transmitted frames is maintained by IFG settings or the truncated binary exponential backoff algorithm. After the IFG and backoff condition are met, the MAC enables transmission.

The IFG setting ensures an idle period between two transmitted frames, i.e., the configured inter-frame gap (IFG bit in the ETH\_MAC\_CONFIGR register). If a frame to be transmitted arrives before the configured IFG time, the MII waits for the enable signal from the MAC before starting transmission. Whenever the carrier signal of the MII becomes inactive, the MAC starts the IFG counter. When the IFG count equals the set value, the MAC enables transmission in full-duplex mode.

In half-duplex mode, when the IFG is configured as 96 bit times, the MAC follows the compliance rules specified in the IEEE802.3 standard. If a carrier is detected during the first two-thirds of the IFG interval (64 bit times for all IFG values), the MAC resets its IFG counter. If a carrier is detected during the last third of the IFG interval, the MAC continues the IFG count and enables the transmitter after the IFG interval ends.

In half-duplex mode, the truncated binary exponential backoff algorithm is implemented, controlled by the BL bit setting in the MAC configuration register (ETH\_MAC\_CONFIGR).

## Retransmission During Collision

In half-duplex mode, a collision event may occur on the MAC line interface during frame transmission to the MAC. The MAC may indicate a retry even before receiving the end of frame status, then enable retransmission and send the frame from the Tx FIFO again.

After more than 96 bytes are delivered to the MAC core, the Tx FIFO controller releases the space, allowing the DMA to deliver more data. This means retransmission is not possible after exceeding the threshold or when the MAC core indicates a delayed collision event.

## TxFIFO Flush

The MAC controller can empty the Tx FIFO by setting the FTF bit in the Operation Mode Register (ETH\_DMA\_OPRMODR). The emptying operation is immediate; even if the Tx FIFO is transmitting a frame to the MAC core, the Tx FIFO and its pointers is cleared to the initial state. This can cause an underflow event in the MAC transmitter, aborting frame transmission, and the frame status marks both underflow and flush events (FFF bit and UDE bit in TDES0). During the emptying operation, no data is transferred from the TxDMA to the Tx FIFO. The TxDMA transmits the corresponding number of transmission status words to the application based on the number of flushed frames (including partial frames). The frame flush status bit (FFF bit in TDES0) is set to 1 for fully flushed frames. The emptying operation is completed when the TxDMA accepts the status words of all flushed frames, and the FTF bit then is cleared. At this point, new frames from the TxDMA is accepted. After the emptying operation is completed, all submitted data is discarded unless the data starts with an SOF mark.

## CRC Processing and PAD Generation

When the number of bytes received from the application is less than 60 (DA+SA+LT+data), zeros (PAD) can be appended to the transmitted frame by resetting the DPAD bit in the transmit descriptor TDES0, making the data length exactly 46 bytes to meet the IEEE802.3 minimum data field requirement, or no padding can be added.

The MAC also calculates the cyclic redundancy check (CRC) for the frame check sequence (FCS) field. Depending on the settings of the DCRC bit and CRCR bit in the transmit descriptor TDES0, the checksum

value can be inserted or replaced into the transmitted data. For details, refer to "Normal Tx Descriptor" and "Enhanced Tx Descriptor".

**Note**

When the CRC replacement function is enabled, the enhanced Tx descriptor must be enabled.

If the MAC is programmed not to append the CRC value to the end of the Ethernet frame, the calculated CRC is not sent. However, when the DPAD bit in TDES0 is 0, frames smaller than 60 bytes (DA+SA+LT+data) have padding PAD appended after the data, and the CRC result is also automatically appended to the end of the padded frame.

### Source Address (SA) Processing

If the data from the application does not contain a source address field, the MAC can insert this field; if it contains a source address field, the MAC can choose to replace it with the values set in MAC Address Registers 0-1. The specific handling of the SA field can be controlled by the SAIRC bit in the MAC configuration register (ETH\_MAC\_CONFIGR) or the SAIRC bit in descriptor TDES1.

**Note**

When this function is enabled via the descriptor method, the enhanced Tx descriptor must be enabled.

### VLAN Tag Handling

The MAC can also insert, replace, or delete the identifier field of VLAN frames from the application. The specific handling can be controlled by the VLANC bit in the VLAN mark transmit control register (ETH\_MAC\_VTACTLR) or the VLANC bit in descriptor TDES0.

**Note**

When this function is enabled via the descriptor method, the enhanced Tx descriptor must be enabled.

### Transmit Status Word

At the end of Ethernet frame transmission to the MAC core, and after the core completes frame transmission, the transmission status is provided to the application via the transmit descriptor. For details on the transmission status, refer to bit [17:0] in TDES0. If the IEEE1588 timestamp function is enabled, a 64-bit timestamp for the specific frame is returned along with the transmission status.

### Pause Frame Transmission

In full-duplex mode, when the transmit flow control enable bit (TFE bit in ETH\_MAC\_FLOCTL) is set to 1, the MAC generates pause frames and send them as needed. Pause frames are sent along with the calculated CRC. Pause frame generation can be initiated in two ways.

- By setting the FCA bit in the ETH\_MAC\_FLOCTL register to 1 to request flow control, the MAC generates and send a single pause frame. The pause time value in the generated frame is the programmed pause time value in ETH\_MAC\_FLOCTL. To extend or end the pause time before the time specified in the previously sent pause frame, the user must program the PAUSET pause time value in the ETH\_MAC\_FLOCTL register with an appropriate value in the application, then request another pause frame transmission.
- When the Rx FIFO is full and the application has requested flow control, the MAC generates and send pause frames. The pause time value in the generated frame is the programmed pause time value in ETH\_MAC\_FLOCTL. If the Rx FIFO remains full during the configurable number of slots (PLT bit in ETH\_MAC\_FLOCTL) before this pause time ends, a second pause frame is sent. This process repeats

as long as the Rx FIFO remains full. If this condition is no longer met before the pause time ends, the MAC transmits a pause frame with a pause time of zero to indicate to the remote port that the Rx FIFO is ready to receive new data frames.

## COE Engine

In network interconnection, basic communication protocols (e.g., TCP and UDP) implement checksums and include checksum fields, which help determine the integrity of data sent over the network. Since the most common use of Ethernet is to package TCP and UDP in IP datagrams, the Ethernet MAC controller has a checksum offload function (COE engine), which supports checksum calculation and insertion in the transmit path, and checksum calculation and detection in the receive path. This section describes the operation of the COE engine in transmission; Section 30.4.1.3.6 describes its operation in reception.

The COE engine calculates the checksum for TCP, UDP, or ICMP over the complete frame and inserts it into the checksum field of the header. Due to this requirement, this function is enabled only when the Tx FIFO is configured in store-and-forward mode (TSF bit in ETH\_DMA\_OPRMODR register set to 1). If the core is configured in threshold mode, the COE engine is bypassed.

The Tx FIFO must be deep enough to store a complete frame for transmission to the MAC core Transmitter. If the FIFO depth is smaller than the input Ethernet frame size, the TCP/UDP/ICMP checksum insertion function is bypassed, and only the IPv4 header checksum insertion function is supported, even in store-and-forward mode.

Control of the transmit checksum offload function can be achieved by setting the CIC bits (TDES0[23:22]) for checksum control per frame.

### ● IP Header Checksum

In IPv4 datagrams, the integrity of the header fields is indicated by a 16-bit header checksum field (bytes 11 and 12 of the IPv4 datagram). The COE engine detects an IPv4 datagram when the Ethernet frame's type field is 0x0800 and the IP datagram's version field is 0x4. During calculation, the checksum field of the input frame is ignored and replaced with the calculated value. IPv6 headers do not have a checksum field, so the COE does not modify IPv6 header fields. The result of the IPv4 header checksum calculation is indicated by the IP header error status bit (IHE bit in TDES0) in the transmission status. This status bit is set to 1 whenever the Ethernet type field value and IP header version field value are inconsistent, or when the Ethernet frame does not have enough data (as indicated by the IP header length field).

Therefore, in summary, IP header errors occur under the following conditions:

1. For IPv4 datagrams:
  - ▶ Ethernet type is 0x0800, but the IP header version field is not equal to 0x4.
  - ▶ The IPv4 header length field indicates a value less than 0x5 (20 bytes).
  - ▶ The total frame length is less than the value given by the IPv4 header length field.
2. For IPv6 datagrams:
  - ▶ The Ethernet type is 0x86DD, but the IP header version field is not equal to 0x6
  - ▶ The frame ends before the IPv6 header (40 bytes), or the extension header is fully received (as given by the corresponding header length field in the extension header).

If the Ethernet type field indicates an IPv4 payload, the IPv4 header checksum is inserted even if the COE engine detects an IP header error.

### ● TCP/UDP/ICMP Checksum

The TCP/UDP/ICMP checksum function processes IPv4 or IPv6 headers (including extension headers) and determines whether the encapsulated payload is TCP, UDP, or ICMP.

The COE engine is disabled in the following two cases:

1. Non-TCP, non-UDP or non-ICMP/ICMPv6 payloads.
2. Fragmented IP frames (IPv4 or IPv6), IP frames with safety functions (e.g., authentication headers or encapsulated safety payloads), and IPv6 frames with routing headers.

When the COE engine is enabled, it calculates the checksum for TCP, UDP, or ICMP payloads and inserts it into the corresponding field in the header. It can operate in the following two ways:

1. The TCP, UDP or ICMPv6 pseudo-header is not included in the checksum calculation and is assumed to exist in the checksum field of the input frame. The checksum field is included in the checksum calculation and then replaced with the final calculated checksum.
2. The TCP, UDP, or ICMPv6 pseudo-header is included in the checksum calculation, the checksum field is ignored, and the checksum field is overwritten with the final calculated value.

#### Note

For ICMP-over-IPv4 packets, since no pseudo-header is defined for them, the checksum field in the ICMP packet must always be 0x0000 in both modes. If it is not equal to 0x0000, an incorrect checksum may be inserted into the packet.

The result of this operation is indicated by the payload error status bit (TPCE bit in TDES0) in the transmit descriptor. The TPCE bit is set to 1 when one of the following is detected:

1. In store-and-forward mode, the frame is forwarded to the MAC transmitter, but the end of the frame is written to the Rx FIFO.
2. The packet ends before receiving the number of bytes indicated by the payload length field in the IP header.

#### Note

When the packet length is greater than the indicated payload length, the extra bytes are ignored as padding, and no error is reported. When the first type of error is detected, the TCP, UDP, or ICMP headers are not modified. For the second type of error, the calculated checksum is still inserted into the corresponding header field.

### Transmission Timing

In the RMII interface, each nibble from the MII is sent on the RMII as two bits at a time, with the transmission order of the two bits as shown in the figure below. The lower-order bits (D0 and D1) are sent first, followed by the higher-order bits (D2 and D3).

Figure 38-6 MII/RMII Transmission Bit Order

The following shows the basic transmission timing diagram.

Figure 38-7 Collision-Free Transmission Diagram

Figure 38-8 Collision Transmission Diagram

Figure 38-9 Transmission Diagram in MII/RMII Mode

### 38.3.3.4 MAC Frame Reception Action

Frames received by the MAC controller are sent to the Rx FIFO. When reception meets certain conditions, the RxDMA is instructed to perform data transfer, and the RxDMA can initiate preconfigured burst transfers on the AHB interface.

The Ethernet MAC controller is equipped with a 2KB Rx FIFO. RxDMA has two operating modes for transferring data from Rx FIFO to system memory:

In threshold mode, when the number of bytes received by the Rx FIFO exceeds the configured receive threshold (configured using the RTC bit in the ETH\_DMA\_OPRMODR register) or a complete packet is received, data transfer is initiated, and its availability is notified to the RxDMA. After the RxDMA initiates a transfer on the AHB interface, data transfer continues from the Rx FIFO until the entire packet is transmitted. After the transmission of the EOF frame is completed, the receive status word is returned and sent to the RxDMA controller. In this mode, some error frames are not discarded because the error status is received at the end of the frame, by which time the data is already transferred from the Rx FIFO to the system memory.

In store-and-forward mode, frames can only be read after they are completely written to the Rx FIFO. In this mode, all error frames are discarded (if the core is configured to do so), so only active frames are read and forwarded to the application.

The status is immediately available after receive data, so frames can be stored in the Rx FIFO as long as it is not full.

The MAC starts the receive operation when it detects the SFD on the MII. The MAC core removes the header and SFD before further processing the frame. Header fields are checked for filtering, and the FCS field is used to verify the frame's CRC. If the frame does not pass the address filter, it is discarded in the core.

### Basic Protocol Reception

When the MAC receives receive data, it first removes the header and SFD from the received frame. After detecting the SFD, it starts sending Ethernet frame data to the Rx FIFO, beginning with the first byte after the SFD (destination address). If the IEEE1588 timestamp function is enabled, a snapshot of the system time is captured when the SFD of any frame is detected on the MII. Unless the MAC filters out and discards the frame, this timestamp is passed to the application.

If the received frame's length/type field is less than 0x600 and the MAC is programmed with the automatic CRC/PAD removal option, the MAC transmits frame data to the Rx FIFO (no more than the amount specified in the length/type field), then start discarding bytes (including the FCS field). If the

length/type field is greater than or equal to 0x600, the MAC transmits all received Ethernet frame data to the Rx FIFO, regardless of the programmed automatic CRC removal option.

By default, the MAC watchdog timer is enabled, meaning frames exceeding 2048 bytes (DA+SA+LT+data+PAD+FCS) is cut off. This function can be disabled by programming the watchdog disable (MWD) bit in the MAC configuration register (ETH\_MAC\_CONFIGR). However, even if the watchdog timer is disabled, frames larger than 16KB is still cut off, and a watchdog timeout status is given.

### Reception Error Handling

If the Rx FIFO becomes full before receiving EOF data from the MAC, an overflow is declared, and the entire frame is discarded, while the overflow counter in the Frame Loss Statistics Register (ETH\_DMA\_RFR CNTR) increases. Due to the overflow, the status indicates that this is a partial frame. If the corresponding functions are enabled (FEF and FUF bits in ETH\_DMA\_OPRMODR), the Rx FIFO can filter error frames and undersized frames.

In threshold mode, when reading the frame SOF from the Rx FIFO, basic information about the current frame can be obtained. By comparing it with the basic settings of the Rx descriptor, it can be determined whether the frame is an error frame, and the entire error frame can be discarded. In store-and-forward mode, all error frames can be filtered and discarded before data transfer.

### CRC Calculation and PAD Removal

The MAC core calculates the 32-bit CRC of the received frame (including the destination address field to the FCS field) and check for any CRC errors in the received frame. Regardless of whether automatic CRC/PAD removal is enabled (controlled by the ACS bit in the ETH\_MAC\_CONFIGR register), the MAC receives the entire frame to calculate the CRC check of the received frame and feed the result back to the application via the CRE bit in the receive descriptor RDES0.

### Reception Status Word

At the end of Ethernet frame reception, the MAC outputs the receive status, which is sent via the RxDMA to the receive descriptor RDES0 for application reference.

### Pause Frame Reception

During frame transmission, the MAC detects received pause frames and pause frame transmission for the delay specified in the received pause frame (full-duplex mode only). Pause frame detection function can be enabled or disabled via the RFE bit in ETH\_MAC\_FLOCTL R. After receive flow control is enabled, monitoring starts to check whether the destination address of the received frame matches the multicast address of control frames (0x0180C2000001). If a match is detected (the destination address of the received frame matches the reserved control frame's destination address), the MAC decides whether to transmit the received control frame to the application based on the PCF bit in ETH\_MAC\_FLTCTLR.

The MAC also decodes the type, opcode, and pause timer fields of the received control frame. If the status byte counting indicates 64 bytes and there are no CRC errors, the MAC transmitter pauses any data frame transmission for the pause time value decoded multiplied by the slot time (64 byte times for 10/100Mbps modes). At the same time, if another pause frame with a zero pause time value is detected, the MAC resets the pause time and manage the new pause request. If the received control frame does not match the type field (0x8808), opcode (0x00001), and byte length (64 bytes), or if there is a CRC error, the MAC does not generate a pause.

For pause frames with multicast destination addresses, the MAC filters frames based on address matching. For pause frames with unicast destination addresses, the MAC filters based on whether the DA field matches the content of MAC Address Register 0 and whether the UNP bit in ETH\_MAC\_FLOCTL R is set

to 1 (detecting pause frames with unicast destination addresses). The PCF bit in the ETH\_MAC\_FLTCTLR register controls filtering of control frames and address filtering.

### COE Engine

The Ethernet MAC controller supports detection and processing of IPv4 and IPv6 frames in received Ethernet frames to ensure data integrity. The receive COE engine is enabled by setting the IPCO bit in the ETH\_MAC\_CONFIGR register to 1. The MAC identifies IPv4 or IPv6 frames by checking whether the type field of the received Ethernet frame contains the value 0x0800 or 0x86DD. This identification method also applies to frames with VLAN marks.

The receive COE engine can calculate the IPv4 header checksum and check whether it matches the received IPv4 header checksum. If there is any mismatch between the indicated payload type (Ethernet type field) and the IP header version, or if the number of bytes in the received frame is less than the amount indicated in the IPv4 header's length field (fewer than 20 bytes available in the IPv4 or IPv6 header), the IP header error bit is set to 1.

The receive COE engine can also identify TCP, UDP, or ICMP payloads in received IP datagrams (IPv4 or IPv6) and correctly calculate the checksum fields for such payloads, including TCP/UDP/ICMPv6 pseudo-header bytes for checksum calculation, and check whether the received checksum field matches the calculated value. The result of this operation is given by the IP payload error bit in receive descriptor RDES4. If the length of the TCP, UDP, or ICMP payload does not match the expected payload length given in the IP header, this status bit is also set to 1.

The COE engine bypasses payloads of fragmented IP datagrams, IP datagrams with safety functions, IPv6 routing headers, and payloads other than TCP, UDP, or ICMP.

### Reception Timing

In the RMII interface, each nibble inside the MAC is sent from the two bits received from the RMII to the MII, with the nibble transmission order as shown in the figure below. The lower-order bits (D0 and D1) are received first, followed by the higher-order bits (D2 and D3).

Figure 38-10 MII/RMII Reception Bit Order

The following shows the basic transmission timing diagram.

Figure 38-11 Error-Free Transmission Diagram

Figure 38-12 Error Transmission Diagram

Figure 38-13 Reception Diagram Under False Carrier Indication

### 38.3.3.5 MAC Frame Filtering

The MAC can filter various received frames to select those needed by the application. Frame filtering methods include the following:

1. Filtering by destination address and source address of MAC frames.
2. Filtering by identifier of VLAN frames.
3. Filtering by source address and destination address of LAY3 IP packets.
4. Filtering by source port and destination port of LAY4 TCP and UDP packets.

The basic descriptions of each filtering method are introduced in the following sections:

#### MAC Source Address Filtering

The MAC can perform perfect filtering based on the source address field of the received frame. By default, the MAC compares the SA field with the values programmed in the MAC Address Register. MAC Address Registers 1-4 can be configured to compare the SA field by setting bit 30 (SA) in the MAC Address Register to 1. If the SAF bit in the Frame Filter Control Register (ETH\_MAC\_FLTCTLR) is set to 1, the MAC discards frames that fail SA filtering. Otherwise, the result of SA filtering is given by the status bit in the receive status word (see receive descriptor word RDES0).

Note: When the SAF bit is set to 1, the results of SA filtering and DA filtering are performed AND operations to determine whether to forward the frame. This means that if either filtering fails, the frame is discarded. Both filtering processes must pass for the frame to be forwarded to the application.

When the ETHMAC controller compares each byte of the address value in MAC Address Registers 1-4 with the corresponding SA byte of the received frame, it can mask the byte by setting the corresponding control bit in the register to 1, thereby achieving group address filtering for the SA.

For source address filtering, the filtering match result can be inverted at the final output, meaning that a match in the SA address comparison is considered a filtering failure. This function is controlled by the SAIF bit in the Frame Filter Control Register (ETH\_MAC\_FLTCTLR).

### MAC Destination Address Filtering-Unicast

The MAC supports up to 5 MAC destination addresses for unicast filtering. If perfect filtering is selected (HUC bit in the Frame Filter Control Register set to 0), the MAC compares all 48 bits of the received unicast destination address with the programmed MAC address to determine a match. By default, MAC Address Register 0 is always enabled, while other MAC Address Registers 1-4 are selected via individual enable bits.

When the ETHMAC controller compares each byte of MAC Address Registers 1-4 with the corresponding DA byte of the received frame, it can mask the byte by setting the corresponding control bit in the register, thereby achieving group address filtering for the DA.

### MAC Destination Address Filtering-Multicast

By setting the PMF bit in the Frame Filter Control Register to 1, the MAC is programmed to pass all multicast frames. If the PAM bit is reset, the MAC performs filtering of multicast addresses based on the HMC bit in the Frame Filter Register. In perfect filtering mode, multicast addresses are compared with the programmed MAC Address Registers 1-4. This filtering method also supports group address filtering.

### MAC Destination Address Filtering-Broadcast

In default mode, the MAC does not filter any broadcast frames. However, if the DBF bit in the Frame Filter Register is set to 1 to program the MAC to reject all broadcast frames, any broadcast frame is discarded.

For destination address filtering (unicast, multicast, broadcast), the filtering match result can also be inverted at the final output, meaning that a match in the DA address comparison is considered a filtering failure. This function is controlled by the DAIF bit in the Frame Filter Control Register (ETH\_MAC\_FLTCTLR) and also applies to Hash filtering results.

### MAC Destination Address Hash Filtering

Hash filtering is also supported for unicast and multicast destination address filtering. In Hash filtering mode (HUC bit/HMC bit set to 1), the MAC uses a 64-bit Hash table to perform imperfect filtering of unicast or multicast addresses, i.e., Hash filtering. For Hash filtering, the MAC uses the 6 high-order CRC bits of the received destination address to index the contents of the Hash table. A value of 000000 selects bit 0 in the selected register, and a value of 111111 selects bit 63 in the Hash table register. If the corresponding bit (indicated by the 6-bit CRC) is set to 1, the unicast or multicast frame is considered to have passed Hash filtering; otherwise, the frame is considered to have failed Hash filtering.

#### Note

CRC is a 32-bit value encoded using the following polynomial:

$$G(x)=x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$$

## VLAN Identifier Filtering

When the received frame is a VLAN frame, the MAC can enable filtering of the VLAN identifier field by setting the VTFE bit in the Frame Filter Control Register (ETH\_MAC\_FLTCTLR). The comparison value for filtering is set in the VLFLT bit of the VLAN Tag Acceptance Filter Register (ETH\_MAC\_VTAFLTR), and the VTAL bit in this register can be set to choose whether to filter the entire VLAN identifier field or only the lower 12 bits.

For VLAN identifier field filtering, the filtering match result can also be inverted at the final output, meaning that a match in the identifier field comparison is considered a filtering failure. This function is controlled by the VTIM bit in the VLAN Tag Acceptance Filter Register (ETH\_MAC\_VTAFLTR) and also applies to Hash filtering results.

## VLAN Identifier Hash Filtering

Hash filtering can also be selected for VLAN identifier filtering. In Hash filtering mode (VTHM bit in ETH\_MAC\_VTAFLTR set to 1), the MAC uses a 16-bit Hash table to perform imperfect filtering of VLAN identifiers, i.e., Hash filtering. For Hash filtering, the MAC uses the CRC bits of the VLAN identifier to index the contents of the Hash table. A value of 1 indicates passing VLAN identifier filtering; a value of 0 indicates failing VLAN identifier filtering.

### Note

CRC is a 32-bit value encoded using the following polynomial:

$$G(x) = x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$$

## L3 Source Address & Destination Address Filtering

Filtering by source address and destination address is also supported for received LAY3 IPv4 and IPv6 packets. The L3SAM bit and L3DAM bit in the LAY3LAY4 Control Register can enable source address filtering and destination address filtering, respectively. The comparison values for the source address or destination address are set in the LAY3 Address Registers (L3ADDR0-3). For details, refer to the register description.

LAY3 IP address filtering can optionally mask high-order bits to achieve group address filtering. The high-order bit masking filtering control for source address and destination address is controlled by the HSBM and HDBM bits in the LAY3LAY4 Control Register (ETH\_MAC\_L34CTLR), respectively.

For LAY3 IP packet address filtering, the filtering match result can also be inverted at the final output, meaning that a match in the address field comparison is considered a filtering failure. This function is controlled by the L3SAIM and L3DAIM bits in the LAY3LAY4 Control Register (ETH\_MAC\_L34CTLR).

## L4 Source Port & Destination Port Filtering

Filtering by source port and destination port is also supported for received LAY4 TCP and UDP packets. The L4SPM bit and L4DPM bit in the LAY3LAY4 Control Register can enable source port filtering and destination port filtering, respectively. The comparison values for the source port or destination port are set in the LAY4 Port Register (L4PORTR). For details, refer to the register description.

For LAY4 TCP and UDP packet port filtering, the filtering match result can also be inverted at the final output, meaning that a match in the port field comparison is considered a filtering failure. This function is controlled by the L4SPIM and L3DPIM bits in the LAY3LAY4 Control Register (ETH\_MAC\_L34CTLR).

### 38.3.3.6 MAC Loopback Mode

The MAC supports looping back frames sent to its receiver. By default, the MAC loopback function is disabled. It can be enabled by programming the LM bit in the MAC control register (ETH\_MAC\_CONFIGR).

### 38.3.3.7 MAC Management Counter (MMC)

The MAC Management Counter (MMC) is equipped with a set of Registers to collect statistics about received and transmitted frames. This includes a Control Register (ETH\_MMC\_MMCTLR) to control the behavior of each register, two 32-bit registers (ETH\_MMC\_REVSTSR and ETH\_MMC\_TRSSTSR) containing current receive and transmit statistics, two 32-bit registers (ETH\_MMC\_RITCTLR and ETH\_MMC\_TITCTLR) containing receive and transmit interrupt control, and statistical registers for various frame types. These statistical registers can be accessed from the application. The purpose and significance of these statistical registers are described in detail in the register chapter. Please refer to the ETH\_MMC register chapter.

The MAC management counter (MMC) updates the corresponding statistical registers for received frames that pass address filtering. Statistics for discarded frames are not updated unless the discarded frame is an undersized frame smaller than 6 bytes (DA bytes cannot be fully received).

If a frame is transmitted successfully, it is considered a "Good Frame". That is, a transmitted frame is considered a "Good Frame" if the transmission process is not aborted due to the following errors:

- Jabber timeout
- No carrier/carrier loss
- Late collision
- Frame underrun
- Excessive delay
- Excessive collisions

If a frame is received successfully, it is considered a "Good Frame." That is, a received frame is considered a "Good Frame" if it does not have the following errors:

- CRC error
- Undersized frame (shorter than 64 bytes)
- Alignment error (only for 10/100 Mb/s)
- Length error (non-type frames only)
- Out of range (only for non-type frames, exceeding maximum size)
- MII\_RXER input error

#### Note

The maximum frame size depends on the frame type, as follows:

- Maximum bytes for non-identifier frames: 1518
- Maximum bytes for VLAN frames: 1522

### 38.3.3.8 MAC Power Management (PMT)

The ETHMAC controller supports the Power Management (PMT) mechanism. The PMT module can be enabled via the remote wake-up frame enable bit and the magic packet enable bit. These enable bits (WKEN and MPEN) are located in the ETH\_MAC\_PMTCTLR register and can be programmed by the application. When Power-down mode is enabled (ETH\_MAC\_PMTCTLR.PWDN=1), the MAC discards all received frames and not forward them to the application. The MAC controller exits Power-down mode

only when the corresponding detection bit is enabled and the corresponding magic packet or remote wake-up frame is received.

### Remote Wake-Up Frame Filtering

The ETHMAC controller has 8 wake-up frame filter registers. To perform a write operation on each register, the Remote Wake-Up Frame Filter Register (ETH\_MAC\_RTWKFFR) must be loaded with values one by one. By loading the Remote Wake-Up Frame Filter Register eight times consecutively, the desired values can be loaded into the register. The read operation is similar to the write operation. To read eight values, the Wake-Up Frame Filter Register must be read eight times to reach the last register. Each read/write operation points the Wake-Up Frame Filter Register pointer to the next filter register. The current read/write operation's filter register can be determined by reading the RTWKPT bit in the PMT Control Status Register (ETH\_MAC\_PMTCTLR). The internal pointer can be reset by setting the RTWKFR bit in this register to 1, after which the Remote Wake-Up Frame Filter Register can be operated again. The figure below shows the 8 internal Remote Wake-Up Frame Filter Registers of the ETHMAC.

|                          |                   |                 |                |                 |                |                 |                |                 |
|--------------------------|-------------------|-----------------|----------------|-----------------|----------------|-----------------|----------------|-----------------|
| <i>ETH_MAC_RTWKFFR 0</i> | FLT0<br>Byte Mask |                 |                |                 |                |                 |                |                 |
| <i>ETH_MAC_RTWKFFR 1</i> | FLT1<br>Byte Mask |                 |                |                 |                |                 |                |                 |
| <i>ETH_MAC_RTWKFFR 2</i> | FLT2<br>Byte Mask |                 |                |                 |                |                 |                |                 |
| <i>ETH_MAC_RTWKFFR 3</i> | FLT3<br>Byte Mask |                 |                |                 |                |                 |                |                 |
| <i>ETH_MAC_RTWKFFR 4</i> | -<br>Command      | FLT3<br>Command | -<br>Command   | FLT2<br>Command | -<br>Command   | FLT1<br>Command | -<br>Command   | FLT0<br>Command |

| <i>ETH_MAC_RTWKFFR 7</i> | FLT3<br>CRC16     |                 |                |                 | FLT2<br>CRC16  |                 |                |                 |

Figure 38-14 Remote Wake-Up Frame Filter Registers

The Function descriptions of each part in the above figure are as follows:

- Filter i Byte Mask

This register defines which bytes of the frame filter i checks to determine whether the frame is a wake-up frame (i=0-3). The MSB (bit 31) must be zero, and bits j[30:0] are the byte mask. If bit j (byte count) of the byte mask is set to 1, the filter i offset + j of the incoming frame is processed by the CRC module; otherwise, filter i offset + j is ignored.

- Filter i Command

This 4-bit command controls filter i operation (i=0-3). Bit3 is the address type selection: when set, only multicast frames are detected; otherwise, only unicast frames are detected. Bit2 and Bit1 are reserved bits. Bit0 is the enable bit for filter i: when set, filter i is enabled; otherwise, it is disabled.

- Filter i Offset

This register defines the offset of the frame to be detected by filter i (i=0-3). This 8-bit pattern offset is the offset of the first byte to be detected by filter i. The minimum value allowed is 12, representing the 13th byte of the frame (offset value 0 represents the first byte of the frame).

- Filter i CRC-16

This register contains the pre-written CRC-16 value (i=0-3) for comparison with the CRC-16 value calculated from the frame data (after filter i Offset and corresponding Byte Mask).

The generator polynomial of CRC-16 is:  $G(x)=x^{16} + x^{15} + x^2 + 1$ .

### Remote Wake-Up Frame Detection

When the MAC is in Power-down mode and the remote wake-up bit WKEN in the PMT Control Status Register (ETH\_MAC\_PMTCTLR) is set to 1, the MAC can resume normal operation after receiving a remote wake-up frame. The PMT supports four programmable filters, which can be configured by the application for different receive frame patterns. A wake-up frame can be received if the incoming frame passes the filter's address filtering and the filter's CRC-16 matches the incoming detection pattern. Only the wake-up frame needs to be checked for length errors, FCS errors, frame tail errors, MII errors, and collisions to ensure it is not an undersized frame. Even if the wake-up frame exceeds 512 bytes, the frame is enable as long as its CRC value is enable.

The wake-up frame detection status bit (WKFR) in the ETH\_MAC\_PMTCTLR register is updated for each received remote wake-up frame. Additionally, a PMT Interrupt is generated (if enabled) to indicate that a remote wake-up frame is received.

### Magic Packet Detection

The magic packet is based on AMD's magic packet technology to power on devices on the network that are in Sleep mode. The MAC receives a specific packet called a magic packet, whose destination address is a node on the network. The MAC controller only checks magic packets with destination addresses matching this device or multicast addresses to determine whether these packets meet the wake-up requirements. Magic packets that pass address filtering (unicast or multicast) are checked to determine whether they conform to the remote wake-up data format: a packet with 6 bytes of all "1" bits plus the MAC address repeated 16 times.

The application enables magic packet wake-up by writing 1 to the MPEN bit in the ETH\_MAC\_PMTCTLR register. The PMT module continuously monitors each frame whose destination address corresponds to the specified magic packet pattern. It checks whether the destination address and source address fields of each received frame are followed by a synchronization stream in the form of 0xFFFFFFFFFFFF. Then, the PMT module checks whether the frame contains the MAC address repeated 16 times without any breaks or interrupts. If there is an interrupt in the 16 repeated addresses, the incoming frame is scanned again for the 0xFFFFFFFFFFFF pattern. These 16 repetitions can be located anywhere in the frame but must follow the synchronization stream (0xFFFFFFFFFFFF). As long as the MAC address repeated 16 times is detected, the device can receive multicast frames. For example, if the node's MAC address is 0x001122334455, the data sequence scanned by the MAC is:

```
Destination Address Source Address... FFFF FFFF FFFF
0011 2233 4455 0011 2233 4455 0011 2233 4455 0011 2233 4455
0011 2233 4455 0011 2233 4455 0011 2233 4455 0011 2233 4455
0011 2233 4455 0011 2233 4455 0011 2233 4455 0011 2233 4455

... CRC
```

Then, it is considered that a magic wake-up packet is received. The magic packet detection in the ETH\_MAC\_PMTCTLR register is updated for received magic packets. Additionally, a PMT interrupt is generated (if enabled) to indicate that a magic packet is received.

### System State During Power-down

1. The MAC receiver should remain enabled during Power-down mode because it needs to perform related reception detection for magic packets/remote wake-up frames. The MAC receiver is enabled by setting the RE bit in the ETH\_MAC\_CONFIGR register to 1.
2. The MAC transmitter should remain off during Power-down mode. The MAC transmitter is turned off by clearing the TE bit in the ETH\_MAC\_CONFIGR register.
3. The Ethernet DMA should be disabled during Power-down mode because there is no need to copy magic packets/network wake-up frames to system memory at this time. The TxDMA and RxDMA are disabled by clearing the STT bit and STR bit in the ETH\_DMA\_OPRMODR register.

The recommended Power-down and wake-up sequence is as follows:

- Step1.** Disable TxDMA and wait for all previous frame transmissions to complete;
- Step2.** Disable the MAC transmitter and MAC receiver by clearing the RE bit and TE bit in the ETH\_MAC\_CONFIGR register;
- Step3.** Wait for the RxDMA to empty all frames in the Rx FIFO;
- Step4.** RxDMA disabled;
- Step5.** Enable magic packet/remote wake-up frame detection by setting the MPEN/WKEN bit in the ETH\_MAC\_PMTCTLR register to 1;
- Step6.** Enable MAC Power-down mode by setting the PWDN bit in the ETH\_MAC\_PMTCTLR register to 1;
- Step7.** Enable the MAC receiver by setting the RE bit in the ETH\_MAC\_CONFIGR register to 1;
- Step8.** Waiting for receiving magic packet and remote wakeup frame;
- Step9.** When a active wake-up frame is received, the Ethernet controller exits Power-down mode;
- Step10.** Read ETH\_MAC\_PMTCTLR to clear the PMT event flag, and enable the MAC transmitter, TxDMA, and RxDMA.

## 38.3.4 ETH\_PTP Function

### 38.3.4.1 ETH\_PTP Function Overview

The IEEE1588 standard defines a protocol that supports precise clock synchronization in measurement and control systems implemented using technologies such as network communication, local computing, and distributed objects. This protocol is suitable for systems that communicate using local area networks (including but not limited to Ethernet) that support multicast messaging. This protocol is used to synchronize non-uniform systems that contain clocks with varying inherent accuracy, resolution, and stability. This protocol supports system-level synchronization accuracy in the sub-second range and requires minimal network and local clock computing resources. This message-based protocol is called the Precision Time Protocol (PTP), and it is transmitted over UDP/IP. Systems or networks are classified as master and slave nodes for distributing timing/clock information. This protocol synchronizes slave nodes with the master node by exchanging PTP messages, as shown in the figure below.

Figure 38-15 Clock Synchronization Diagram

1. The master node broadcasts PTP sync messages to all its nodes. The sync message contains the reference time information of the master node. The time when the message leaves the master node system is  $t_1$ . For Ethernet ports, this time must be captured via the MII interface;
2. The slave node receives the sync message and captures the precise time  $t_2$  using its reference timing;
3. The master node then sends a Follow\_Up message containing  $t_1$  information to the slave node for later use;
4. The slave node sends a Delay\_Req message to the master node, marking the precise time  $t_3$  when the frame leaves the MII;
5. The master node receives this message and captures the precise time  $t_4$  when the message enters its system;
6. The master node sends the  $t_4$  information in a Delay\_Resp message to the slave node;
7. The slave node uses these four values ( $t_1$ ,  $t_2$ ,  $t_3$ , and  $t_4$ ) to synchronize its local reference timing with the master node's reference timing.

Although most protocols are implemented in software above the UDP layer, hardware is required to capture the precise time when specific PTP packets enter or leave the Ethernet port via the MII interface.

#### 38.3.4.2 PTP Reference Timing Source

According to the IEEE1588 specification, to obtain a time snapshot, the core requires a 64-bit format reference time (divided into two 32-bit channels: the high 32 bits represent seconds, and the low 32 bits represent sub-seconds).

The PTP reference clock input is used to internally generate the reference time (also called system time) and capture timestamps. The frequency of this reference clock must be greater than or equal to the resolution of the timestamp counter. The target synchronization accuracy between the master node and slave nodes is approximately 100ns. Accuracy depends on the PTP reference clock input period, the oscillator's features (drift), and the frequency of the synchronization process.

Due to synchronization from the Tx and Rx clock input domains to the PTP reference clock domain, the uncertainty of the timestamp latch value is 1 reference clock period. If the uncertainty caused by resolution is added, it increases by half the timestamp period.

#### 38.3.4.3 PTP Message Types

After the timestamp function is enabled, the TSPMTSEL bit in the Timestamp Control Register (ETH\_PTP\_TSPCTLR) can control which message or type of message to take a timestamp snapshot of. The specific correspondence is shown in the table below.

**Table 38-7 Timestamp Snapshot Target Frames**

| TSPMTSEL[3:0] | Timestamp-Enabled Frame Types                                                          |
|---------------|----------------------------------------------------------------------------------------|
| 0b00X0        | SYNC, Follow_Up, Delay_Req, Delay_Resp                                                 |
| 0b0001        | SYNC                                                                                   |
| 0b0011        | Delay_Req                                                                              |
| 0b01X0        | SYNC, Follow_Up, Delay_Req, Delay_Resp, Pdelay_Req, Pdelay_Resp, Pdelay_Resp_Follow_Up |
| 0b0101        | SYNC, Pdelay_Req, Pdelay_Resp                                                          |
| 0b0111        | Delay_Req, Pdelay_Req, Pdelay_Resp                                                     |
| 0b10XX        | SYNC, Delay_Req                                                                        |
| 0b11XX        | Pdelay_Req, Pdelay_Resp                                                                |

#### 38.3.4.4 PTP Frame Transmission Function

The timestamp is captured when the SFD of the frame is output on the MII. For frames requiring timestamp capture, each transmitted frame can be marked to indicate whether it is necessary to capture its timestamp.

PTP frames can be identified without processing the transmitted frames; frame control can be performed via the control bit in the transmit descriptor.

The captured timestamp is returned to the application in the same way as the frame status is provided. The timestamp is sent back along with the frame's transmission status to the corresponding transmit descriptor, automatically associating the timestamp with the specific PTP frame. The 64-bit timestamp information is written back to the TDES6 and TDES7 fields, with TDES6 holding the 32 least significant bits of the timestamp.

#### 38.3.4.5 PTP Frame Reception Function

When the IEEE1588 timestamp function is enabled, the Ethernet MAC captures timestamps for all frames received on the MII. The MAC provides the timestamp when the frame reception process is completed.

The captured timestamp is returned to the application in the same way as the frame status is provided. The timestamp is sent back along with the frame's receive status to the corresponding receive descriptor. The 64-bit timestamp information is written back to the RDES6 and RDES7 fields, with RDES6 holding the 32 least significant bits of the timestamp.

#### 38.3.4.6 PTP System Time Adjustment

The 64-bit PTP time is updated using the PTP input reference clock. This PTP time can be used as a clock source to capture snapshots (timestamps) of Ethernet frames transmitted or received on the MII. The system time timer can be initialized or calibrated using coarse or fine calibration methods.

In coarse calibration mode, the initial value or offset value is written to the timestamp update register. For initialization, the value in the timestamp update register is written to the system time counter; for system time calibration, the offset value (timestamp update register) is added to or subtracted from the system time.

In fine calibration mode, the offset of the reference clock frequency relative to the master clock (as defined in IEEE1588) is calibrated over a period of time, unlike coarse calibration, which is done within a single clock period. The longer the calibration time, the better it helps maintain linear time and prevents large variations (or jitter) in the reference time between PTP synchronization message intervals. In this method, an accumulator is used to sum the contents of the basic addend register (ETH\_PTP\_TSPADDR), as shown in the figure below. The arithmetic carry generated by the accumulator is used as a pulse to increment the system time counter. Both the accumulator and the basic addend register are 32-bit registers. Here, the accumulator serves as a high-precision frequency multiplier or divider.

Figure 38-16 System Time Calibration

The system time update logic requires a 50MHz clock frequency to achieve 20ns accuracy. The frequency dividing ratio is the ratio of the reference clock frequency to the desired clock frequency. If the reference clock frequency is 66MHz, the frequency dividing ratio is calculated as  $66\text{MHz}/50\text{MHz}=1.32$ , and the default addend value set in the basic addend register is  $2^{32}/1.32$ , equivalent to 0xC1F07C1F. If the reference clock drifts down to 65MHz, the frequency dividing ratio becomes  $65\text{MHz}/50\text{MHz}=1.3$ , and the value to be set in the basic addend register is  $2^{32}/1.3$ , equivalent to 0xC4EC4EC4. If the clock drifts up to 67MHz, the basic addend register must be set to 0xBF0B7672. When the clock offset is zero, the default addend value to be programmed is 0xC1F07C1F ( $2^{32}/1.32$ ).

The value used to increment the sub-second addend register is set to the decimal number 43. This enables the system time accuracy to reach 20ns (in other words, the incremental step time is 20ns).

The software must calculate the frequency offset based on the sync message and update the basic addend register accordingly. First, the slave clock is set using FreqCompensationValue0 in the basic addend register. The formula for this value is as follows:

$$\text{FreqCompensationValue0} = 2^{32} / \text{FreqDivisionRatio}$$

If it is initially assumed that MasterToSlaveDelay is the same for consecutive sync messages, the following algorithm must be applied. After several synchronization periods, the frequency locks. The slave clock can then determine the precise value of MasterToSlaveDelay and resynchronize with the master clock using the new value.

The algorithm is as follows:

- At MasterSyncTime(n), the master clock sends a sync message to the slave clock. The slave clock receives this message at its local clock time SlaveClockTime(n) and calculates MasterClockTime(n) using the following formula:  

$$\text{MasterClockTime}(n) = \text{MasterSyncTime}(n) + \text{MasterToSlaveDelay}(n)$$
- The master clock counting MasterClockCount(n) for the current sync period is calculated as follows:  

$$\text{MasterClockCount}(n) = \text{MasterClockTime}(n) - \text{MasterClockTime}(n-1)$$
 (Assuming MasterToSlaveDelay is the same for sync periods n and n-1)
- The slave clock counting SlaveClockCount(n) for the current sync period is calculated as follows:  

$$\text{SlaveClockCount}(n) = \text{SlaveClockTime}(n) - \text{SlaveClockTime}(n-1)$$
- The difference in master-slave clock counting SlaveClockCount(n) for the current sync period is calculated as follows:  

$$\text{ClockDiffCount}(n) = \text{MasterClockCount}(n) - \text{SlaveClockCount}(n)$$
- The slave clock's frequency dividing coefficient FreqScaleFactor(n) is calculated as follows:  

$$\text{FreqScaleFactor}(n) = (\text{MasterClockCount}(n) + \text{ClockDiffCount}(n)) / \text{SlaveClockCount}(n)$$
- The frequency compensation value FreqCompensationValue(n) for the addend register is calculated as follows:  

$$\text{FreqCompensationValue}(n) = \text{FreqScaleFactor}(n) \times \text{FreqCompensationValue}(n-1)$$

Theoretically, this algorithm can achieve lock within one sync period, but due to varying network propagation delays and operating conditions, multiple periods may be required.

This algorithm can self-calibrate: if the slave clock initially set by the master clock is incorrect for some reason, the algorithm spends more sync periods calibrating it.

#### 38.3.4.7 PTP System Time Generation Initialization

The timestamp function is enabled by setting the TSPEN bit in the timestamp control register (ETH\_PTP\_TSPCTLR) to 1. However, the timestamp counter must then be initialized to start timestamp operations. The setup sequence is as follows:

- Step1.** Mask the timestamp-triggered interrupt by setting the TSPIM bit in the ETH\_MAC\_INTMSKR register to 1.
- Step2.** Program the TSPEN bit in the ETH\_PTP\_TSPCTLR register to enable the timestamp.
- Step3.** Program the sub-second addend register (ETH\_PTP\_TAPNSAR) based on the PTP clock frequency.
- Step4.** Program the basic addend register (ETH\_PTP\_TSPADDR) and set the TSPADUP bit in the timestamp control register to 1 (basic addend register update).
- Step5.** Poll the timestamp control register to confirm the TSPADUP bit is cleared.
- Step6.** To select fine calibration mode, set the TSPUPSEL bit in the timestamp control register to 1.

- Step7.** Program the timestamp update second register and timestamp update sub-second register with appropriate time values.
- Step8.** Set the TSPINI bit in the timestamp control register to 1 (timestamp initialization).
- Step9.** After initializing the timestamp counter with the value written in the timestamp update register, the timestamp counter begins running.
- Step10.** Enable the MAC receiver and transmitter for the timestamp function to operate normally.

#### 38.3.4.8 PTP PPS Output

The PTP module can output the generated internal clock via PPS (PPS0) to the ETH\_PTP\_PPS port (continuous output mode) for clock synchronization of all nodes in the network system. There are also two PPS outputs (PPS0 and PPS1) (single output mode), which can serve as event outputs to control other blocks.

In PPS continuous output mode, after the system time undergoes second carry (sub-second time Overflow), the PPS0 channel can generate a series of specific pulses or clocks for external network node clock synchronization. The specific output pulse or output clock frequency is set by the PPSFRE0 bit in the PPS output control register (ETH\_PTP\_PPSCTLR). Only the PPS0 channel supports continuous output mode.

In PPS single output mode, if the system time equals the time set in target time register 0 or target time register 1, a pulse can be generated on the PPS0 or PPS1 channel, respectively. This function is only enabled when the TT0SEL bit or TT1SEL bit in the PPS output control register (ETH\_PTP\_PPSCTLR) is set; it is activated when the PPSFRE0 bit or PPSFRE1 bit in the PPS output control register (ETH\_PTP\_PPSCTLR) is set. After the pulse is generated, to generate another pulse output, the target time register 0/1 and the PPSFRE0/1 bits in the PPS output control register must be reset.

For example, users can link the event output of PPS0 or PPS1 in single output mode with Timer2 as needed. For specific implementation, refer to the "General Timer (Timer2) " and "Interrupt Controller (INTC) " chapters. This linkage with Timer2 has two main purposes:

1. When the system time equals the target time, the trigger interrupt provided by the MAC introduces a known delay, causing uncertainty in command execution time. During the period from interrupt trigger to command execution, the timing function of Timer2 can be used to obtain an accurate interrupt processing delay time.
2. System time deviation calibration. PPS outputs a fixed-time pulse, which is detected using Timer2's pulse width measurement function. The PPS system time is adjusted based on Timer2's measurement feedback to calibrate the PTP internal system time.

#### 38.3.5 ETH\_DMA Function

##### 38.3.5.1 ETH\_DMA Function Overview

The ETHMAC controller DMA has independent transmit and receive engines. The transmit engine transfers data from system memory to the Tx FIFO, while the receive engine transfers data from the Rx FIFO to system memory. The DMA can efficiently transfer data between FIFOs and system memory via descriptors without any CPU intervention. The DMA controller can be programmed by the application to generate CPU interrupts upon completion of frame transmission and reception operations or under other normal/error conditions. Therefore, it can be seen that the ETHMAC controller DMA and MCU core communicate via two data structures:

- Control and Status Registers
- Descriptor Lists and Data Buffers

The DMA can transfer data frames received by the MAC to the system's data buffer or send data from the system's data buffer to the MAC. The descriptors contain pointers to these data buffers. The DMA has two descriptor lists: an Rx descriptor list for reception and a Tx descriptor list for transmission. The base addresses of the Rx and Tx descriptor lists are set via the descriptor list registers (ETH\_DMA\_RXDLADR and ETH\_DMA\_TXDLADR), respectively. The descriptor list is a forward-linked list (either implicit or explicit), with the last descriptor pointing back to the first to form a ring structure. The descriptor list resides in the system's physical memory space.

Each descriptor can point to up to two buffers, allowing two physically addressed buffers to replace two contiguous buffers in memory. Explicit linking of descriptors is achieved by configuring the second linked address in the Rx and Tx descriptors (RDES1[14] and TDES0[20]).

The data buffer also resides in the system's physical memory space, typically consisting of an entire frame or part of a frame but never exceeding a single frame. The data buffer contains only data, the status of data communication is stored in the descriptor. When the end of a frame is detected, the DMA jumps to the next frame buffer. Data linking allows frames to span multiple data buffers and can be enabled or disabled. Descriptors have two structure types: ring structure and link structure, as shown in the figure below.

Figure 38-17 Descriptor Structure

### 38.3.5.2 DMA Initialization

The initialization steps for DMA are as follows:

- Step1.** Perform a write operation on ETH\_DMA\_BUSMODR to set bus access parameters;
- Step2.** Perform a write operation on the ETH\_DMA\_INTENAR register to mask unnecessary interrupt sources;
- Step3.** Create descriptor lists and perform write operations on the ETH\_DMA\_RXDLADR and ETH\_DMA\_TXDLADR registers to provide the DMA with the start address of each list;

- Step4.** Perform write operations on the MAC register to set the desired filtering options;
- Step5.** Perform a write operation on the ETH\_MAC\_CONFIGR register to configure and enable transmit and receive operating modes;
- Step6.** Perform a write operation on the ETH\_DMA\_OPRMODR register, setting the STT bit and STR bit to 1 to start transmission and reception;
- Step7.** The transmit and receive engines enter the running state and attempt to fetch descriptors from their respective descriptor lists. These engines then start processing receive and transmit operations. The transmit and receive processes are independent of each other and can be started or stopped separately.

### Bus Burst Access

The DMA attempts to perform fixed-length burst transfers on the AHB Master interface (when the FBST bit in ETH\_DMA\_BUSMODR is configured accordingly). The maximum burst length is indicated and limited by the TPBL or RPBL fields (ETH\_DMA\_BUSMODR [13:8] and [22:17]). For the 16 bytes to be read, the receive and transmit descriptors are always accessed using the maximum possible burst size.

The TxDMA initiates data transfer only when there is enough space in the Tx FIFO to accommodate the configured burst or the number of bytes before the end of the frame (when the frame is shorter than the configured burst length). The TxDMA indicates the start address and the required number of transfers to the AHB master interface. When the AHB interface is configured for fixed-length bursts, the optimal combination of INCR4, INCR8, INCR16, and SINGLE is used to transfer data. Otherwise (non-fixed-length bursts), INCR (undefined length) and SINGLE is used to transfer data.

RxDMA initiates data transfer only when there is sufficient data in the Rx FIFO for the configured burst, or when a frame end is detected in the Rx FIFO (when the frame is shorter than the configured burst length). RxDMA indicates the start address and the number of transfers required to the AHB Master interface. When the AHB interface is configured for fixed-length bursts, the optimal combination of INCR4, INCR8, INCR16, and SINGLE is used to transfer data. If the frame end is reached before the fixed burst on the AHB interface ends, a empty transfer is performed to complete the fixed-length burst transfer. Otherwise (for non-fixed length bursts), INCR (undefined length) and SINGLE is used to transfer data.

When the AHB interface is configured for address-aligned beats (ETH\_DMA\_BUSMODR.AAL=1), the two DMA engines ensures that the first burst transfer initiated by the AHB is less than or equal to the size of the configured PBL. In this way, all subsequent beats starts from an address aligned with the configured PBL. Due to AHB interface transfers exceeding INCR16, the DMA can only align addresses up to a maximum of 16 beats (PBL>16).

### Data Buffer Alignment

There are no restrictions on the start address alignment for transmit and receive data buffers. The start address of the buffer can be aligned with any of the four bytes. However, the DMA always initiates transfers when the address is aligned with the bus width and transmits empty data on unnecessary byte lanes. This typically occurs during the start or end of an Ethernet frame transfer.

- **Buffer Read Operation Example:**

If the transmit buffer address is 0x00000FF2 and 15 bytes need to be transferred, the TxDMA reads five full words from address 0x00000FF0, but discards or ignore the extra bytes (the first two bytes) when transferring the data to the Tx FIFO. Similarly, the last three bytes of the last transfer is also ignored. The TxDMA always ensures that full 32-bit data is transferred to the Tx FIFO, unless it is the end of the frame.

- Buffer Write Operation Example:

If the receive buffer address is 0x0000FF2 and 16 bytes of the received frame need to be transferred, the RxDMA starts writing five full 32-bit data from address 0x0000FF0. However, the first two bytes of the first transfer and the last two bytes of the third transfer contains empty data.

### Buffer Size Calculation

The Ethernet controller DMA does not update the buffer size field in the transmit and receive descriptors, but only updates the status field of the descriptors. The application must use the driver to calculate the buffer size.

The TxDMA transmits the exact number of bytes to the MAC core (indicated by the buffer size field in TDES1). If the descriptor is marked as the first descriptor (by setting the TFS bit in TDES0 to 1), the DMA marks the first transfer of the buffer as the start of the frame. If the descriptor is marked as the last descriptor (by setting the TLS bit in TDES0 to 1), the DMA marks the last transfer of the data buffer as the end of the frame.

The RxDMA continues to transfer data to the buffer until the buffer is full or the end of the frame is received. When the RFS bit of the descriptor is set to 1, if the descriptor is not marked as the last descriptor (the RLS bit in RDES0), the corresponding buffer of the descriptor is filled, and the amount of active data is indicated by the buffer size in RDES1. If the descriptor is marked as the last descriptor, the buffer is not filled, and the amount of active data is represented by the result obtained by subtracting the data buffer pointer offset (the FRAL bit in RDES0) from the buffer size field. When the data buffer pointer is aligned with the data bus width, the offset is zero.

#### Note

Even when the start address of the receive buffer is not aligned with the system data bus width, the system should allocate a receive buffer whose size is aligned with the system bus width. For example, if the system allocates a receive buffer with a start address of 0x1000 and a size of 1024 bytes (1 KB), the software can program the buffer start address in the receive descriptor to have an offset of 0x1002. The RxDMA writes the frame into the buffer, where the first two units (0x1000 and 0x1001) contain empty data. The actual frame starts writing from unit 0x1002. Therefore, although the buffer size is programmed to 1024 bytes, due to the presence of the start offset address, the actual usable space of the buffer is 1022 bytes.

### DMA Arbiter

The arbiter within the Ethernet controller DMA arbitrates between accesses to the AHB Master interface by the transmit and receive channels. Two types of arbitration can be used: round-robin priority and fixed priority. If round-robin priority arbitration (ETH\_DMA\_BUSMODR.DMAA=0) is selected, the arbiter allocates the data bus according to the priority method and ratio set by the ETH\_DMA\_BUSMODR.TXPR and PTAT bits when the transmit and receive DMA simultaneously request access. If fixed priority arbitration (ETH\_DMA\_BUSMODR.DMAA=1) is selected, the arbiter allocates the data bus according to the priority method set by the ETH\_DMA\_BUSMODR.TXPR bit when the transmit and receive DMA simultaneously request access.

#### 38.3.5.3 DMA Error Response

For any data transfer initiated by a DMA channel, if the slave responds with an error, the corresponding DMA stops all operations and update the error bit and fatal bus error bit in the status register (ETH\_DMA\_DMASTR). At this point, the DMA controller can only resume operation after a soft reset or hard reset of the peripheral and reinitialization of the DMA.

### 38.3.5.4 DMA Transmit Configuration

#### TxDMA Operation

During the continuous frame transfer process, the TxDMA processes the second frame differently based on the setting of the OSF bit in the operation mode register (ETH\_DMA\_OPRMODR). When the OSF bit is set to 1, after the transmission of the first frame is completed, the transmit process immediately polls the transmit descriptor list of the second frame. If the second frame is enabled, the transmit process transmits the second frame before writing the status information of the first frame. This type of transmit process, which can obtain two frames simultaneously without closing the status descriptor of the first frame, is called OSF mode. The opposite is non-OSF mode.

The operation sequence of the TxDMA engine when ETH\_DMA\_OPRMODR.OSF=0 is as follows:

- Step1.** After the data buffer is set with the corresponding Ethernet frame data, the user configures the transmit descriptors (TDES0-TDES3) and sets the OWN bit (TDES0[31]) to 1.
- Step2.** After setting the STT bit (ETH\_DMA\_OPRMODR register [13]) to 1, the DMA immediately enters the running state.
- Step3.** In the running state, the DMA polls the transmit descriptor list for the frame to be transferred. After polling starts, the DMA continues in a continuous circular order of descriptors or linked order. If the DMA detects a descriptor marked as owned by the CPU (TDES0.OWN=0) or an error condition occurs, it suspends the transfer and set the transmit buffer unavailable bit (ETH\_DMA\_DMASTR register TUS bit) and the normal interrupt summary enable bit (ETH\_DMA\_DMASTR register AIS bit) to 1. The transmit engine continues to execute step 9.
- Step4.** If the obtained descriptor is marked as owned by the DMA (TDES0.OWN=1), the DMA decodes the transmit data buffer address according to the obtained descriptor.
- Step5.** The DMA fetches the transmit data from the system memory and transfers these data.
- Step6.** If the Ethernet frame is stored in the data buffers of multiple descriptors, the DMA closes the intermediate descriptor and obtain the next descriptor. Repeat steps 3, 4, and 5 until the Ethernet frame data transfer is completed.
- Step7.** After the frame transfer is completed, if the IEEE1588 timestamp is enabled for the frame (as indicated in the transmit status), the timestamp value is written into the transmit descriptors (TDES6 and TDES7), and then the status information is written into the status bits (TDES0) of the transmit descriptor. In this step, the OWN bit is cleared, and the descriptor becomes owned by the CPU.
- Step8.** After the frame transmission is completed, when the last descriptor bit (TDES0.TLS) is set to 1, the TIS bit of the DMA action status register is set to 1. The DMA engine then returns to step 3.
- Step9.** In the suspended state, the DMA attempts to reacquire the descriptor (return to step 3) upon receiving a transmit poll request and clears the underflow interrupt status bit.

The action flowchart of TxDMA in non-OSF mode is shown in the figure below.

Figure 38-18 TxDMA Workflow (Non-OSF Mode)

The operation sequence of the TxDMA engine when ETH\_DMA\_OPRMODR.OSF=1 is as follows:

- Step1.** The operation process of the DMA is as described in steps 1 to 6 of the TxDMA in non-OSF mode.
- Step2.** Without closing the last descriptor of the previous frame, the DMA can obtain the next descriptor.
- Step3.** If the DMA owns the required descriptor, it decodes the transmit buffer address in the descriptor. If the DMA does not own the descriptor, it enters the suspended mode and jump to step 7.
- Step4.** The DMA fetches the transmit frame from the system memory and sends the frame until the end of the frame data transmission. If the frame is split into multiple descriptors, the intermediate descriptors is closed simultaneously.
- Step5.** The DMA waits for the transmission status and timestamp of the previous frame. When the status is available, if the timestamp (indicated by the status bit) is captured, the DMA writes these timestamps into TDES6 and TDES7. Then, the OWN bit is cleared, the DMA writes the

status into the corresponding TDES0, and then closes the descriptor. If the timestamp is not enabled for the previous frame, the DMA does not change the content of TDES6 and TDES7.

- Step6.** If the timestamp is enabled, the transmit interrupt is set to 1, the DMA obtains the next descriptor, and then continue to execute step 3 (when the status is normal). If the previous transmit status shows an underflow error, the DMA enters the suspended mode (step 7).
- Step7.** In the suspended mode, if the DMA receives the suspended status and timestamp, it writes the timestamp (if the timestamp is enabled for the current frame) into TDES6 and TDES7, and then write the status into the corresponding TDES0. Then, the relevant interrupt is set to 1 and the suspended mode is returned.
- Step8.** Only after receiving the transmit poll request (ETH\_DMA\_TXPOLLR register), the DMA exits the suspended mode and enters the running state (go to step 1 or step 2, depending on the suspended status).

The action flowchart of TxDMA in OSF mode is shown in the figure below.

Figure 38-19 TxDMA Workflow (OSF Mode)

## Transmit Frame Handling

The system data buffer must contain the complete Ethernet frame, excluding the header, PAD, and FCS fields, and the DA, SA, and type/length fields must be included in the active data. If the transmit descriptor indicates that the MAC core must prohibit the insertion of CRC or padding bytes, the buffer must have a complete Ethernet frame including the CRC bytes (excluding the header). The frame can be in the form of data linking or span multiple buffers. The frame must be bounded by the first descriptor bit (TDES0.TFS) and the last descriptor bit (TDES0.TLS). When the transmission is initiated, the TDES0.TFS of the first descriptor must be set to 1, and then the frame data is transmitted from the memory buffer to the Tx FIFO. At the same time, if the TDES0.TLS of the current frame is 0, the transmit process attempts to obtain the next descriptor. If TDES0.TLS is 0, it indicates the intermediate buffer, and if TDES0.TLS is 1, it indicates the last buffer of the frame. After the last buffer of the frame is transmitted, the DMA writes the final status information back to the relevant status bit (TDES0) of the descriptor. At this time, if the TDES0.IOC bit is set to 1, the TIS bit of the transmit status register is set to 1, the next descriptor is obtained, and then the process is repeated.

Depending on the setting of the TSF bit in the ETH\_DMA\_OPRMODR register, the actual frame transmission process is initiated when the Tx FIFO reaches the programmable transmit threshold (TTC bit in the ETH\_DMA\_OPRMODR register) or when the Tx FIFO contains a complete frame. After the DMA completes the frame transmission, the descriptor is released (the TDES0.OWN bit is cleared).

## Transmit Poll Suspend

The transmit poll can be suspended by any of the following conditions:

- The DMA detects a descriptor owned by the CPU (TDES0[31]=0), and the transmit buffer unavailable flag TUS in the ETH\_DMA\_DMASTR register is set to 1. To resume, the driver must hand over the ownership of the descriptor to the DMA and then issue a poll query request command.
- When a transmission error caused by underflow is detected, the frame transmission is aborted. The corresponding transmit descriptor (TDES0) bit is set to 1.

If the DMA enters the suspended state due to the first condition, the normal interrupt summary bit and the transmit buffer unavailable bit (NIS and TUS bits in the ETH\_DMA\_DMASTR register) of the transmit status register are both set to 1. If the second condition occurs, the abnormal interrupt summary bit and the transmit underflow bit (AIS and UNS bits in the ETH\_DMA\_DMASTR register) are both be set to 1, and the information is written into the transmit descriptor, causing the suspension. In both cases, the positions in the transmit list is retained. The retained position is the descriptor position following the last descriptor closed by the DMA. After correcting the cause of the suspension, the driver must explicitly issue a transmit poll request command.

## Normal Tx Descriptor

The normal Tx descriptor consists of four 32-bit words, as shown in the table below. These words are defined as TDES0, TDES1, TDES2, and TDES3.

Table 38-8 Normal Tx Descriptor

| Descriptor Structure | Bit Position |     |     |     |      |      |      |      |     |    |     |      |       |    |      |     |       |     |     |      |      |     |      |     |     |   |     |   |   |   |     |     |     |

The specific bits of TDES0-TDES3 are explained below.

● The functions of each bit in TDES0 are as follows:

| Bit | Name | Function                      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-----|------|-------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31  | OWN  | All Related Bits              | <p>► 0b0: The descriptor is owned by the CPU</p> <p>► 0b1: The descriptor is owned by the DMA</p> <p>The DMA clears this bit after completing the frame transmission or after reading all the buffers assigned to the descriptor.</p> <p>After setting all subsequent descriptors of the same frame to 1, the OWN bit of the first descriptor of the frame should also be set to 1.</p>                                                                      |
| 30  | IOC  | End of Transmission Interrupt | <p>When this bit is set to 1, the TIS bit in the action status register is set to 1 after the current frame is transmitted.</p> <div>  <b>Note</b><br/>           This bit is only valid when the last descriptor bit (TDES0.TLS) is set to 1.         </div>                                                                                                               |
| 29  | TLS  | Last Descriptor               | This bit indicates that the descriptor contains the last buffer of the frame.                                                                                                                                                                                                                                                                                                                                                                                |
| 28  | TFS  | First Descriptor              | This bit indicates that the descriptor contains the first buffer of the frame. If the size of the first buffer is 0, the second buffer contains the frame header; if the size of the second buffer is 0, the next descriptor contains the frame header                                                                                                                                                                                                       |
| 27  | DCRC | Invalid CRC                   | <p>When this bit is set to 1, the MAC does not append the cyclic redundancy check (CRC) to the end of the transmitted frame.</p> <div>  <b>Note</b><br/>           This bit is only valid when the first descriptor bit (TDES0.TFS) is set to 1.         </div>                                                                                                           |
| 26  | DPAD | Invalid PAD                   | <p>► 0b0: The DMA automatically adds padding and CRC to frames less than 64 bytes, regardless of the setting of the DCRC bit in the descriptor.</p> <p>► 0b1: The MAC does not automatically add padding to frames less than 64 bytes.</p> <div>  <b>Note</b><br/>           This bit is only valid when the first descriptor bit (TDES0.TFS) is set to 1.         </div> |
| 25  | TTSE | Timestamp enabled             | <p>When this bit is set to 1, the IEEE1588 hardware timestamp function is activated for the transmit frame described by the descriptor.</p> <div>  <b>Note</b><br/>           This bit is only valid when the first descriptor bit (TDES0.TFS) is set to 1.         </div>                                                                                                |

| Bit   | Name  | Function                   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-------|-------|----------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 24    | CRCR  | CRC Replacement Control    | <p>When this bit is set to 1, the MAC replaces the FCS field of the transmit frame to be sent with the calculated CRC value.</p> <div>  <b>Note</b><br/>           This bit is only valid when the TDES0.DCRC bit of the descriptor is set to 1.         </div>                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 23:22 | CIC   | Checksum Insertion Control | <p>These bits control the calculation and insertion of the checksum as follows:</p> <ul style="list-style-type: none"> <li>▶ 0b00: Disable checksum insertion</li> <li>▶ 0b01: Enable the calculation and insertion of the IP header checksum only</li> <li>▶ 0b10: Enable the calculation and insertion of the IP header checksum and the TCP/UDP/ICMP checksum, but do not calculate the pseudo-header checksum in hardware</li> <li>▶ 0b11: Enable the calculation and insertion of the IP header checksum and the TCP/UDP/ICMP checksum, and calculate the pseudo-header checksum in hardware</li> </ul> <div>  <b>Note</b><br/>           This bit is only valid when the last descriptor bit (TDES0.TLS) is set to 1.         </div> |
| 21    | TER   | End of Ring Transmission   | This bit indicates that the descriptor list has reached its last descriptor, and the DMA returns to the first address of the descriptor list, forming a descriptor ring.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 20    | TSAC  | Second Address Link        | <p>When this bit is set to 1, the second address in the descriptor is the address of the next descriptor, not the second buffer address, and the TBS2 bit of the descriptor is invalid.</p> <div>  <b>Note</b><br/>           The priority of the TER bit is higher than that of the TSAC bit.         </div>                                                                                                                                                                                                                                                                                                                                                                                                                             |

| 31:0 | TBAP2 | Transmit Buffer 2 Address/Next Descriptor Address | This bit indicates to the DMA the location of the data in the memory. When the software provides this descriptor (the OWN bit is set to 1 in TDES0) to the DMA and uses the descriptor ring structure, these bits will indicate the physical address of buffer 2. If the TDES0.TSAC bit is set to 1, this address contains a pointer to the physical register of the next descriptor. <div>  <b>Note</b><br/> The buffer address pointer must match the bus width only when the TDES0.TSAC bit is set to 1. </div> |

### Enhanced Tx Descriptor

When the timestamp function (ETH\_PTP\_TSPCTLR.TSPEN=1) or the checksum offload function (ETH\_MAC\_CONFIGR.IPCO=1) is enabled, an enhanced Tx descriptor should be used.

The enhanced Tx descriptor consists of eight 32-bit words, defined as: TDES0, TDES1, TDES2, TDES3, TDES4, TDES5, TDES6, and TDES7. The functions of TDES0 to TDES3 are the same as those of the conventional type.

Table 38-13 Enhanced Tx Descriptor

The specific bits of TDES0-TDES7 are explained below.

- **Function of each bit of TDES0:** Same as the function of the normal descriptor TDES0.
- **Function of each bit of TDES1:** Same as the function of the normal descriptor TDES1.
- **Function of each bit of TDES2:** Same as the function of the normal descriptor TDES2.
- **Function of each bit of TDES3:** Same as the function of the normal descriptor TDES3.
- **TDES4, TDES5:** Reserved
- **The functions of each bit in TDES6 are as follows:**

| Bit  | Name | Function          | Description                                                                                                                                                                                                                                                                                                                                                                                                                         |
|------|------|-------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31:0 | TTSL | Timestamp Low Bit | <p>The DMA updates this field with the lower 32 bits of the timestamp captured by the corresponding transmit frame.</p> <div>  <b>Note</b><br/>           This field contains the timestamp only when the last descriptor bit (TDES0.TLS) and the transmit timestamp status bit (TDES0.TTSS) in the descriptor are both set to 1.         </div> |

- The functions of each bit in TDES7 are as follows:

| Bit  | Name | Function           | Description                                                                                                                                                                                                                                                                                                                                                                                                                       |
|------|------|--------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31:0 | TTSH | Timestamp High Bit | <p>The DMA updates this field with the upper 32 bits of the timestamp captured by the corresponding transmit frame.</p> <div>  <b>Note</b><br/>           This field contains the timestamp only when the last descriptor bit (TDES0.TLS) and the transmit timestamp status bit (TDES0.TTSS) in the descriptor are both set to 1.         </div> |

### 38.3.5.5 DMA Receive Configuration

#### RxDMA Operation

The operation sequence of the RxDMA engine is as follows:

- Step1.** The user sets the receive descriptors (RDES0-RDES3) and sets the OWN bit (RDES0[31]) to 1.
- Step2.** After setting the ETH\_DMA\_OPRMODR.STR bit in the operation mode register to 1, the DMA enters the running state. In the running state, the DMA polls the receive descriptor list to attempt to obtain an idle descriptor. If the obtained descriptor is not idle (owned by the CPU), the DMA enters the suspended state and jumps to step 9.
- Step3.** The DMA decodes the address of the receive data buffer in the obtained descriptor.
- Step4.** Process the incoming frame and place it into the data buffer of the obtained descriptor.
- Step5.** When the buffer is full or the frame transmission is complete, the receive engine obtains the next descriptor.
- Step6.** If the current frame transmission is complete, the DMA continues to execute step 7. If the DMA does not own the next receive descriptor and the frame transmission is not complete (the EOF field has not been transmitted), the DMA sets the descriptor error bit DPE in RDES0 to 1 (unless refresh is disabled). The DMA closes the current descriptor (clearing the OWN bit) and marks it as an intermediate descriptor by clearing the last descriptor bit (RDES0.RLS) (if refresh is disabled, it marks it as the last descriptor), then continues to execute step 8. If the DMA owns the next descriptor but the current frame transmission is not complete, the DMA closes the current descriptor as an intermediate value and returns to step 4.
- Step7.** If the IEEE1588 timestamp function is enabled, the DMA writes the timestamp (if available) into RDES6 and RDES7 of the current descriptor. The DMA then obtains the status of the received frame and writes this status word into RDES0 of the current descriptor, while clearing the OWN bit and setting the last descriptor bit to 1.
- Step8.** The receive engine checks the OWN bit of the latest descriptor. If the CPU owns the descriptor (OWN bit is 0), the receive buffer unavailable bit (ETH\_DMA\_DMASTR.RUS) is set to 1 and the DMA receive engine enters the suspended state (step 9). If the DMA owns the descriptor, the engine returns to step 4 and waits for the next frame.
- Step9.** Before the receive engine enters the suspended state, some frames is refreshed from the Rx FIFO (refresh can be controlled by the DFRF bit in the ETH\_DMA\_OPRMODR register).
- Step10.** When a receive poll request command is received or the start of the next frame can be obtained from the Rx FIFO, the RxDMA exits the suspended state. The engine continues to execute step 2 and reacquires the next descriptor.

The action flowchart of RxDMA is shown in the figure below.

Figure 38-20 RxDMA Workflow

The receive status of RxDMA is only confirmed after the timestamp is written back and the status is ready to be written back to the descriptor. If the timestamp function is enabled, when the active timestamp value of the frame cannot be obtained (for example, the Rx FIFO is full before writing the timestamp), the DMA writes 1 to all bits of RDES6 and RDES7. If the timestamp function is not enabled, RDES6 and RDES7 remain unchanged.

### Receive Frame Acquisition

The receive engine always tries to obtain an additional descriptor for the incoming frame. As long as any of the following conditions are met, the descriptor is attempted to be obtained:

- After the DMA enters the running state, the receive start/stop bit (ETH\_DMA\_OPRMODR.STR) is immediately set to 1.
- Before the current frame transmission ends, the data buffer of the current descriptor is full.

- The MAC controller has completed the reception of the data frame, but the current receive descriptor has not been closed.
- The receive process is suspended because the descriptor is owned by the CPU (RDES0.OWM=0), and a new frame is received.
- A receive poll request command is issued.

### Receive Frame Processing

When the frame passes address filtering and its size is greater than or equal to the configurable threshold number of bytes set for the Rx FIFO, or when the entire frame is written to the Rx FIFO in store-and-forward mode, the MAC transfers the received frame to the system memory. If the frame does not pass address filtering, it is discarded (unless the receive all bit ETH\_MAC\_FLTCTLR.RA is set to 1). Frames less than 64 bytes may be cleared from the Rx FIFO due to conflicts or premature termination. After receiving 64 (configurable threshold) bytes, the DMA begins to transfer the frame data to the receive buffer specified by the current descriptor. After the DMA AHB interface is ready to receive data transfer, if the DMA has not currently obtained transmit data from memory, the first descriptor bit (RDES0.RFS) is set to 1 to separate the frame. When the data buffer is full or the end of the frame is transmitted to the receive buffer, the OWN (RDES0) bit is reset to 0, and the descriptor is released at this time. If the frame is contained in a single descriptor, both the last descriptor bit (RDES0.RLS) and the first descriptor bit (RDES0.RFS) is set to 1.

When the DMA obtains the descriptor of the next frame, it sets the last descriptor bit (FDES0.RLS) to 1, releases the status bit in the previous frame descriptor, and then sets the receive interrupt bit (ETH\_DMA\_DMASTR register RIS) to 1. This process is repeated until the DMA encounters a descriptor marked as owned by the CPU. In this case, the receive process sets the receive buffer unavailable bit (RUS) in the ETH\_DMA\_DMASTR register to 1, then enters the suspended state, but the position in the receive list is still retained.

### Receive Process Suspend

If a new receive frame arrives while the receive process is in the suspended state, the DMA reacquires the current descriptor in the system memory. If the descriptor is now owned by the DMA, the receive process re-enters the running state and begin to receive the frame. If the descriptor is still owned by the master, by default, the DMA discards the current frame at the top of the Rx FIFO and increment the lost frame counter. If the Rx FIFO stores multiple frames, this process is repeated.

Setting the DFRF bit in the DMA operating mode register (ETH\_DMA\_OPRMODR) to 1 can prevent discarding or refreshing the frame at the top of the Rx FIFO. In this case, the receive process sets the receive buffer unavailable bit (RUS) in the action status register (ETH\_DMA\_DMASTR) to 1 and returns to the suspended state.

## Normal Rx Descriptor

The structure of the normal Rx descriptor consists of four 32-bit words, as shown in the table below, defined as RDES0, RDES1, RDES2, and RDES3 respectively.

Table 38-16 Normal Rx Descriptor

| Descriptor Structure | Bit Position |          |      |    |    |    |    |    |    |    |    |    |    |    |    |    |       |      |          |      |     |      |     |     |             |      |      |     |     |     |     |         |
|----------------------|--------------|----------|------|----|----|----|----|----|----|----|----|----|----|----|----|----|-------|------|----------|------|-----|------|-----|-----|-------------|------|------|-----|-----|-----|-----|---------|

The specific bits of RDES0 to RDES3 are explained below respectively.

● The functions of each bit in RDES0 are as follows:

| Bit   | Name  | Function                              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|-------|-------|---------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31    | OWN   | All related bits                      | <ul style="list-style-type: none"> <li>0b0: The descriptor is owned by the CPU</li> <li>0b1: The descriptor is owned by the DMA</li> </ul> The DMA clears this bit when the frame reception is complete or the associated buffer of this descriptor is full.                                                                                                                                                                                            |
| 30    | DAF   | Destination Address Filtering Failure | This bit indicates that the frame failed the DA filtering in the MAC core.                                                                                                                                                                                                                                                                                                                                                                              |
| 29:16 | FRAL  | Frame Length Statistic                | This bit indicates the byte length of the received frame transmitted to the host memory (including CRC).<br>This field is only valid when the last descriptor bit (RDES0.RLS) is set to 1, and the descriptor error bit (RDES0.DPE) and overflow error bit (RDES0.OVE) are reset.<br>When neither the last descriptor bit nor the error summary bit is set to 1, this field indicates the cumulative number of bytes transmitted for the current frame. |
| 15    | ERSUM | Receive Error Summary                 | If one of the bits Bit[14], Bit[11], Bit[7], Bit[6], Bit[4], Bit[3], Bit[1] of this descriptor and the bits Bit[4] and Bit[3] of the REDS4 descriptor is set, this bit is also set.                                                                                                                                                                                                                                                                     |

| Bit | Name        | Function                         | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

- The functions of each bit in RDES1 are as follows:

| Bit   | Name     | Function                        | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|-------|----------|---------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31    | DIC      | Disable Interrupt on Completion | <p>When this bit is set to 1, it prohibits the host from generating an interrupt when the received frame ends in the buffer indicated by the descriptor, and it also prevents the RIS bit in the action status register (ETH_DMA_DMASTR) from being set to 1.</p> <div>  <b>Note</b><br/>           This bit is only valid when the last descriptor bit (RDES0.RLS) is set to 1.         </div> |
| 30:29 | Reserved | Reserved                        | -                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 28:16 | RBS2     | Buffer 2 Size Field             | <p>This bit indicates the size of the second data buffer in bytes.</p> <div>  <b>Note</b><br/>           This bit is invalid when the RSAC bit of the descriptor is set to 1.         </div>                                                                                                                                                                                                    |
| 15    | RER      | End of Ring Reception           | This bit indicates that the descriptor list has reached its last descriptor, and the DMA returns to the first address of the descriptor list, forming a descriptor ring.                                                                                                                                                                                                                                                                                                         |
| 14    | RSAC     | Second Address Link             | <p>When this bit is set to 1, the second address in the descriptor is the address of the next descriptor, not the second buffer address, and the RBS2 bit of the descriptor is invalid.</p> <div>  <b>Note</b><br/>           The priority of the RER bit is higher than that of the RSAC bit.         </div>                                                                                 |
| 13    | Reserved | Reserved                        | -                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 12:0  | RBS1     | Buffer 1 Size Field             | This bit indicates the size of the first data buffer in bytes. If this field is 0, the DMA ignores this buffer and use buffer 2 or the next descriptor, depending on the setting of RSAC in the descriptor.                                                                                                                                                                                                                                                                      |

● The functions of each bit in RDES2 are as follows:

| Bit  | Name  | Function                 | Description                                                                                                                                                                                                               |
|------|-------|--------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31:0 | RBAP1 | Receive Buffer 1 Address | This bit indicates to the DMA the location of the data in the memory. When the software provides this descriptor (the OWN bit is set to 1 in RDES0) to the DMA, these bits will indicate the physical address of buffer 1 |

● The functions of each bit in RDES3 are as follows:

| Bit  | Name  | Function                                         | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|------|-------|--------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31:0 | RBAP2 | Receive Buffer 2 Address/Next Descriptor Address | <p>This bit indicates to the DMA the location of the data in the memory. When the software provides this descriptor (the OWN bit is set to 1 in RDES0) to the DMA and uses the descriptor ring structure, these bits will indicate the physical address of buffer 2. If the RDES1.RSAC bit is set to 1, this address contains a pointer to the physical register of the next descriptor.</p> <div>  <b>Note</b><br/>           The buffer address pointer must match the bus width only when the RDES1.RSAC bit is set to 1.         </div> |

### Enhanced Rx Descriptor

When the timestamp function (ETH\_PTP\_TSPCTLR.TSPEN=1) or the checksum offload function (ETH\_MAC\_CONFIGR.IPCO=1) is disabled, an enhanced Rx descriptor should be used.

The structure of the enhanced Tx descriptor consists of eight 32-bit words, as shown in the table below, defined as RDES0, RDES1, RDES2, RDES3, RDES4, RDES5, RDES6, and RDES7 respectively. The functions of RDES0 to RDES3 are the same as those of the normal type.

Table 38-21 Enhanced Rx Descriptor

| Descriptor Structure | Bit Position |          |      |    |       |    |       |    |          |    |    |    |    |    |    |    |       |      |          |      |      |      |       |     |             |      |      |     |        |     |        |         |      |  |      |  |      |  |      |  |

The specific bits of RDES0 to RDES7 are explained below respectively.

- **Function of each bit of RDES0:** Same as the function of the normal descriptor RDES0.
- **Function of each bit of RDES1:** Same as the function of the normal descriptor RDES1.
- **Function of each bit of RDES2:** Same as the function of the normal descriptor RDES2.
- **Function of each bit of RDES3:** Same as the function of the normal descriptor RDES3.
- **The functions of each bit in RDES4 are as follows:**

| Bit   | Name     | Function             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

### 38.3.6 Interrupt

#### 38.3.6.1 ETHMAC Interrupt Overview

The figure below shows the interrupt implementation scheme in the Ethernet MAC controller. From the figure, it can be seen that ETHMAC summarizes DMA normal events (NIS), DMA abnormal events (AIS), PMT events (PMTIS), MMC events (MMC\*\*IS), PTP events (TSPIS), etc. into a single interrupt event output to the interrupt module through interrupt enable or mask control. Therefore, when the system responds to an interrupt, it needs to read the corresponding status information to determine which type of event caused the interrupt.

At the same time, the PMT module of ETHMAC also has a non-maskable interrupt output. When a PMT event occurs, a PMT non-maskable interrupt is generated regardless of whether the PMTIM bit in the interrupt mask register (ETH\_MAC\_INTMSKR) is set to 1.

Figure 38-21 ETHMAC Interrupt Scheme

#### 38.3.6.2 DMA Interrupt

Various normal events generated by the DMA during transmit and receive data trigger normal interrupts, and various abnormal events trigger abnormal interrupts. As shown in the figure below.

The interrupt control of each specific event can be controlled by the respective bits in the DMA interrupt enable register ([ETH\\_DMA\\_INTENAR](#)).

Figure 38-22 DMA Interrupt Components

### 38.3.6.3 PMT Interrupt

The MAC can trigger the generation of PMT interrupts (maskable and non-maskable interrupts) when it receives a remote wake-up frame and a magic packet. The generation of maskable interrupts is controlled by the PMTIM bit in the MAC interrupt mask register (ETH\_MAC\_INTMSKR).

### 38.3.6.4 PTP Interrupt

When the PTP function is enabled, a PTP interrupt can be triggered when the system time reaches the set value in the timestamp target time register 0-1. The interrupt is controlled by the TT0SEL and TT1SEL bits of the PPS output control register (ETH\_PTP\_PPSCTLR), the TSPINT bit of the ETH\_PTP timestamp control register (ETH\_PTP\_TSPCTLR), and the TSPIM bit of the MAC interrupt mask register (ETH\_MAC\_INTMSKR).

### 38.3.6.5 MMC Interrupt

MMC interrupts can be triggered when the transmit and receive frame statistics in the MMC overflow. The interrupt is controlled by the respective bits of the MMC Rx interrupt control register (ETH\_MMC\_RITCTLR) and the MMC Tx interrupt control register (ETH\_MMC\_TITCTLR).

## 38.4 Register Description

### 38.4.1 Register List

ETHMAC Common Register Base Address: 0x40055400

Table 38-25 ETHMAC Common Register Offset

| Offset | Register        | Description                          | Width |
|--------|-----------------|--------------------------------------|-------|
| 0x0010 | ETH_MAC_IFCONFR | ETH_MAC Interface Selection Register | 32    |

ETHMAC base address: 0x40060000

Table 38-26 Ethernet MAC Controller (ETHMAC) Register Offset

| Offset | Register         | Description                                  | Width |
|--------|------------------|----------------------------------------------|-------|
| 0x0000 | ETH_MAC_CONFIGR  | ETH_MAC MAC Configuration Register           | 32    |
| 0x0018 | ETH_MAC_FLOCTLR  | ETH_MAC MAC Flow Control Register            | 32    |
| 0x0024 | ETH_MAC_MACSTSR  | ETH_MAC MAC Status Register                  | 32    |
| 0x0038 | ETH_MAC_INTSTSR  | ETH_MAC Interrupt Status Register            | 32    |
| 0x003C | ETH_MAC_INTMSKR  | ETH_MAC Interrupt Mask Register              | 32    |
| 0x0010 | ETH_MAC_SMIADDR  | ETH_MAC SMI Address Register                 | 32    |
| 0x0014 | ETH_MAC_SMIDATR  | ETH_MAC SMI Data Register                    | 32    |
| 0x002C | ETH_MAC_PMTCTLR  | ETH_MAC PMT Control Status Register          | 32    |
| 0x0028 | ETH_MAC_RTWKFFR  | ETH_MAC Remote Wake-Up Frame Filter Register | 32    |
| 0x0004 | ETH_MAC_FLTCTLR  | ETH_MAC MAC Frame Filter Control Register    | 32    |
| 0x0040 | ETH_MAC_MACADHR0 | ETH_MAC MAC Address High Bit Register 0      | 32    |
| 0x0044 | ETH_MAC_MACADLR0 | ETH_MAC MAC Address Low Bit Register 0       | 32    |
| 0x0048 | ETH_MAC_MACADHR1 | ETH_MAC MAC Address High Bit Register 1      | 32    |
| 0x004C | ETH_MAC_MACADLR1 | ETH_MAC MAC Address Low Bit Register 1       | 32    |

| 10    | RTWKTR   | Remote wake-up frame transmission                     | After this bit is set to 1, the MAC no longer receives packets other than magic packets and remote wakeup frames, and forwards the received remote wakeup frames to the application<br><br><div>  <b>Note</b><br/>           1. This bit automatically becomes 0 after receiving a magic packet or remote wakeup frame; it can also be software reset before receiving a magic packet or remote wakeup frame.<br/>           2. When the GLBU bit, WKEN bit, or MPEN bit of this register is 1, and the PWDN bit is 0 at the same time, this bit must be set to 1.<br/>           3. When the PWDN bit is 1, the setting of this bit is disabled.         </div> | RW     |

|------|--------|---------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 31:0 | TXPOLL | Transmit Poll Demand Initiation | <p>Writing any value to this bit causes DMA to read the current descriptor pointed to by the ETH_DMA_CHTXDER register. If the descriptor is unavailable (owned by the host), TxDMA returns to the suspended state and sets the TUS bit of the ETH_DMA_DMASTR register. If the descriptor is available, transmission continues.</p> <p>This register is used to instruct TxDMA to poll the transmit descriptor list and check whether the current descriptor is owned by DMA. If TxDMA is in suspend mode, issue a transmit poll demand command to wake it up. If an underflow error occurs in the transmit frame or the descriptor owned by TxDMA is unavailable, TxDMA enters suspend mode.</p> <p>The user can issue this command at any time. Once the command starts reacquiring the current descriptor from host memory, TxDMA resets it.</p> <div>  <b>Note</b><br/>           This bit reads always returns 0.         </div> | RW     |

## 39 SDIO Controller (SDIOC)

### 39.1 Introduction

SDIOC provides an SD host interface and an MMC host interface for communicating with SD cards supporting the SD2.0 protocol, SDIO devices and MMC devices supporting the eMMC4.2 protocol. This product has 2 SDIO controllers, which can communicate with 2 SD/MMC/SDIO devices at the same time.

### 39.2 Features

- Support SDSC, SDHC, SDXC format SD card and SDIO device
- Supports 1-bit and 4-bit SD bus
- Supports 1-bit, 4-bit and 8-bit MMC buses
- SD clock up to 50MHz
- With card identification and hardware write protection function

## 39.3 Functional Description

### 39.3.1 Port Assignment

Table 39-1 Port Allocation Table

| Port Name | IO  | Function                             |
|-----------|-----|--------------------------------------|
| SDIOx_CK  | O   | SD clock output signal               |
| SDIOx_CMD | I/O | SD command and response signal       |
| SDIOx_D0  | I/O | SD data signal                       |
| SDIOx_D1  | I/O | SD data signal                       |
| SDIOx_D2  | I/O | SD data signal                       |
| SDIOx_D3  | I/O | SD data signal                       |
| SDIOx_D4  | I/O | SD data signal                       |
| SDIOx_D5  | I/O | SD data signal                       |
| SDIOx_D6  | I/O | SD data signal                       |
| SDIOx_D7  | I/O | SD data signal                       |
| SDIOx_CD  | I   | SD card identification status signal |
| SDIOx_WP  | I   | SD write protection status signal    |

#### Note

x represents the unit number, which is 1-2. When x is mentioned in this chapter later, it refers to the unit number and will not be repeated here.

The above ports are based on the SD2.0 protocol and the eMMC4.51 protocol. The SD clock output signal (SDIOx\_CK) is used to output the SD clock when the SDIOC communicates with the SD/MMC device. SD data signal (SDIOx\_Dy (y=0-7) ) is used for SDIOC and devices to send and receive data during communication. When one-wire (1-bit) communication is used, only SDIOx\_D0 is enabled, and SDIOx\_Dy (y=1-7) remains high. When four-wire (4-bit) communication is used, SDIOx\_Dy (y=0-3) is enabled, and SDIOx\_Dy (y=4-7) remains high. When eight-wire (8-bit) communication is used, SDIOx\_Dy (y=0-7) is enable. Eight-wire (8-bit) communication is limited to MMC device communication.

### 39.3.2 Basic Access Method

The user starts the SDIOC to communicate with the off-chip SD/MMC device by reading and writing the SDIOC register. Since writing the command register will trigger the SDIOC's send command action, writing the command register must be done last. Before this, the user needs to set the transmission mode through the transmission mode register (TRANSMODE), set the command parameters through the parameter registers (ARG0, ARG1), and set the correct command number (command index), type, response (response) type, etc. Once the write command register is executed, the SDIOC will send the command, and the user can read the interrupt status register (NORINTST, ERRINTST) to check whether the response information has been received, whether there is an error message, etc. When a command is executed, the user can get the response of the command by reading the response register (RESP0-7).

### 39.3.3 Data Transmission

The data buffer register of SDIOC is used for data exchange between host devices such as CPU/DMA and SD devices. SDIOC has built-in FIFO to speed up data exchange. When the command includes sending data, the user will write the data into the data buffer registers (BUF0, BUF1) sequentially, and these data will be buffered in the FIFO of SDIOC first, when the amount of written data reaches the set value of the data length register (BLKSIZE) or 512 bytes, SDIOC will send data through SDIOx\_Dy (y=0-7). During this period, SDIOC can continue to write data to the data buffer register through FIFO. Similarly, when the command includes data reception, SDIOC receives data through SDIOx\_Dy (y=0-7), and buffers the data in the BUFFER of SDIOC, and the user reads the data buffer registers (BUF0, BUF1) get data. For the data format, please refer to the SD and MMC protocols.

### 39.3.4 SD Clock

The SD clock (SDIOx\_CK) is generated by the host and output to the device for communication between the two. The SD clock is generated by dividing the action clock (PCLK1) of the SDIOC module through a divider. The frequency division coefficient of the frequency divider is set by CLKCON register. According to the requirements of the SD2.0 protocol, the fastest value should be 50MHz in the data transfer mode, so the user needs to set it according to the frequency of PCLK1 reasonable frequency division coefficient.

### 39.3.5 Interrupts and DMA Start Requests

#### SD Interrupt

SDIOC provides two types of interrupts, normal interrupt and error interrupt. Normal interrupts are interrupts that occur when various events occur during the communication between SDIOC and SD/MMC card. Error interrupts are interrupts that are generated when various errors occur during SDIOC operation communication. Normal interrupts and error interrupts have their own interrupt status register, interrupt status enable register, and interrupt signal enable register, respectively.

- The interrupt status register is used to indicate the cause of the interrupt.
- The interrupt status enable register is used to enable each status bit of the interrupt status register. Each status bit of the interrupt status register needs to be active when the enable bit of the interrupt status enable register is enabled.
- The interrupt signal enable register is used to Enable Each interrupt factor to apply for an interrupt to the CPU.

#### SDIO Interrupt

The SDIO device can send a card interrupt request to the host when the transmission is idle. When using SDIO interrupt, you need to enable the NORINTSTEN.CINTEN bit. If you need to apply for an interrupt to the CPU, you also need to enable the NORINTSGEN.CINTEN bit. The SDIO device requests an interrupt from the host by pulling the SDIOx\_D1 data line low. SDIOC detects that SDIOx\_D1 is pulled low, sets the NORINTST.CINT bit, and applies for an interrupt to the CPU according to the setting. The SDIO device will release SDIOx\_D1 after judging that the interrupt processing is completed.

#### DMA Request

SDIOC can read and write data in communication through DMA. When using DMA to transfer and write data to the device, set the start source of a channel of DMA to the write request of SDIOC, and then set the transfer target address of DMA to the data buffer register (BUF0, BUF1) and it is a fixed address. When the SDIOC sends the write data command, if the data FIFO is empty at this time, a write request signal is sent to the DMA, and the DMA is started to write data to the data buffer register (BUF0, BUF1),

and these data will enter the data FIFO in turn. When the data in the FIFO reaches the set value of the data length register (BLKSIZE) or 512 bytes, SDIOC will send the data through SDIOx\_Dy (y=0-7). If it is a multi-block write command, SDIOC will continue to send a start request to the DMA to write data at the same time. When using DMA to transmit data read from the device, set the start source of another channel of DMA to the read request of SDIOC, and then set the transmission source address of DMA to the data buffer register (BUF0, BUF1) and it is a fixed address. After SDIOC sends the read data command, the device will send data through SDIOx\_Dy (y=0-7), and the data FIFO of SDIOC starts to receive data. When the data in FIFO reaches the set value of the data length register (BLKSIZE) or 512 bytes, SDIOC sends a read request signal to DMA, and starts DMA to read data from the data buffer register (BUF0, BUF1). If it is a multi-block read command, SDIOC will continue to read the next data block from the device at the same time.

### Card Insert and Removal

The insert and removal of SD/MMC/SDIO devices are identified by the SDIOx\_CD signal line. When there is no device in the card slot, the card slot will pull up the SDIOx\_CD signal through a resistor. When a device is inserted, the SDIOx\_CD signal will be pulled low, and will become high again after the device is removed. SDIOC judges whether there is a device by the level of SDIOx\_CD. Users can judge whether there is a device plugged in by reading the PSTAT.CDL bit. SDIOC can generate corresponding interrupts when the device is inserted and removed, and is enabled through the NORINTSTEN register and NORINTSGEN register.

## 39.4 Operation Example

### 39.4.1 Host and Device Initialization

#### 39.4.1.1 Host Initialization

##### Context

SDIOC needs to be initialized first when using it.

##### Procedure

- Step1.** Read PSTAT register, query clock status and device insertion status.
- Step2.** Configure PWRCON register, enable SDIOC.
- Step3.** Configure CLKCON register to make SDIOC output the SD clock, and configure the frequency division of the SD clock according to the frequency of PCLK1 to ensure that the frequency of the SD clock in the card identification mode does not exceed 400kHz.
- Step4.** Configure HOSTCON register, select 1-bit mode and disable high speed mode.
- Step5.** Configure TOUTCON register according to the device characteristics, so that the host ends the communication and reports an error when the communication times out.
- Step6.** Configure normal and error interrupt status enable registers, interrupt signal enable register to enable SDIOC to interrupt when needed and set the flag bit.

#### 39.4.1.2 SD Card Initialization

##### Context

After completing the SDIOC initialization configuration, if an SD card is connected, it needs to be initialized according to the SD protocol.

##### Procedure

- Step1.** Card reset, send reset command CMD0 to the device, CMD0 has no response information, at this time the card will enter the card identification mode.

- Step2.** Confirm the operation condition of the card, send CMD8 to the device and wait for the response information.
- Step3.** Send the initialization command ACMD41 (send CMD55 first, then send CMD41), judge whether the device is initialized according to the response information, otherwise continue to send ACMD41 until the initialization is completed.
- Step4.** Send CMD2 to get the CID information of the card.
- Step5.** Send CMD3 to get the RCA information of the card.

#### Results

At this point the card will enter the data transfer mode and the initialization is complete.

#### 39.4.1.3 MMC Card Initialization

##### Context

After completing the SDIOC initialization configuration, if an MMC card is connected, it needs to be initialized according to the MMC protocol.

##### Procedure

- Step1.** Card reset, send reset command CMD0 to the device, CMD0 has no response information, at this time the card will enter the card identification mode.
- Step2.** Confirm the operation condition of the card, send CMD1 to the device and wait for the response message, judge whether the device is initialized according to the response message, otherwise continue to send CMD1 until the initialization is completed.
- Step3.** Send CMD2 to get the CID information of the card.
- Step4.** Send CMD3 to get the RCA information of the card.

#### Results

At this point the card will enter the data transfer mode and the initialization is complete.

#### 39.4.1.4 SDIO Initialization

##### Context

After completing the SDIOC initialization configuration, if an SDIO device is connected, it needs to be initialized according to the SDIO protocol.

##### Procedure

- Step1.** Device reset, send reset command CMD0 to the device, CMD0 has no response information.
- Step2.** Confirm the operation condition of the SDIO device, send CMD5 to the device and wait for the response information.
- Step3.** Send CMD3 to get the RCA information of the device, and the initialization is complete.

#### 39.4.2 SD/MMC Single Block Read and Write

##### Context

After the SD/MMC card enters the data transmission mode, SDIOC can access the data of the SD/MMC card through read and write commands. The order of reading and writing a single data block is as follows:

##### Procedure

- Step1.** Configure CLKCON register to make SDIOC output the SD clock, and configure the frequency division of the SD clock according to the frequency of PCLK1 to ensure that the frequency of the SD clock in the default speed mode does not exceed the maximum clock speed (Default Speed mode,  $f_{pp} \leq 25\text{MHz}$ ).
- Step2.** Send CMD7, SD/MMC card will enter the data transmission state.

- Step3.** If necessary, for the SD card, configure HOSTCON register to set the host bus width, and send ACMD6 to set the SD bus width (1-bit or 4-bit), and for the MMC card, configure HOSTCON register to set the host bus width, and rewrite the Ext\_CSD register of the MMC card through the CMD6 (SWITCH) command to set the bus width (1-bit, 4-bit or 8-bit).
- Step4.** If necessary, for the SD card, you can configure BLKSIZE register to set the data block length, and set the size (bytes) of the data block through the CMD16 command, and the configuration range is 1-512 bytes. For SDHC/SDXC and MMC cards, the data block size is fixed at 512 bytes.
- Step5.** If necessary, for the SD card, configure HOSTCON register to set the host to high speed mode, and send CMD6 to switch the SD card to high speed mode ( $f_{pp} \leq 50\text{MHz}$ ). SDIOx\_CK can be set up to 50MHz after switch success.
- Step6.** When writing data, first configure TRANSMODE register, and set the transfer mode to write, single block transfer. Send single block write command CMD24. If using the CPU to write data, after confirming that the NORINTST.BWR bit is 1, write data to the data buffer register (BUF0, BUF1). If using DMA to write data, wait for the DMA transfer to complete, SDIOC will send data through the data signal SDIOx\_Dy. After the transmission is completed, the NORINTST.TC bit will be set to 1 and an interrupt request will be generated. If an error occurs during the transmission process, the corresponding error flag will be set and an interrupt request will be generated.
- Step7.** When reading data, first configure TRANSMODE register, and set the transfer mode to read, single block transfer. Send single block read command CMD17, SDIOC will receive data through data signal SDIOx\_Dy. If using the CPU to read data, after confirming that the NORINTST.BRR bit is 1, read the data from the data buffer register (BUF0, BUF1). If using DMA to read data, wait for the DMA transfer to complete, after the reading is completed, the NORINTST.TC bit will be set to 1 and an interrupt request will be generated. If an error occurs during the transmission process, the corresponding error flag will be set and an interrupt request will be generated.

### 39.4.3 SD/MMC Multi Block Read and Write

#### Procedure

- Step1.** Configure CLKCON register to make SDIOC output the SD clock, and configure the frequency division of the SD clock according to the frequency of PCLK1 to ensure that the frequency of the SD clock in the default speed mode does not exceed the maximum clock speed (Default Speed mode,  $f_{pp} \leq 25\text{MHz}$ ).
- Step2.** Send CMD7, SD/MMC card will enter the data transmission state.
- Step3.** If necessary, for the SD card, configure HOSTCON register to set the host bus width, and send ACMD6 to set the SD bus width (1-bit or 4-bit), and for the MMC card, configure HOSTCON register to set the host bus width, and rewrite the Ext\_CSD register of the MMC card through the CMD6 (SWITCH) command to set the bus width (1-bit, 4-bit or 8-bit).
- Step4.** If necessary, for the SD card, you can configure BLKSIZE register to set the data block length, and set the size (bytes) of the data block through the CMD16 command, and the configuration range is 1-512 bytes. For SDHC/SDXC and MMC cards, the data block size is fixed at 512 bytes.
- Step5.** Configure TRANSMODE register, set the transfer mode to read/write, and multi-block transfer. If the data block count is enabled, the number of data blocks to be transmitted need to be set in BLKCNT register, multi-block transmission can not start when the BLKCNT register is not

set. If the data block counting enable is disabled, there is no need to set BLKCNT register, meanwhile, an unlimited number of multi-block transmissions can be performed. When the host decides to terminate the transmission, it needs to send a CMD12 to the device after the completion of the last data block transmission to notify the device that the data transmission has ended.

- Step6.** If necessary, for the SD card, configure HOSTCON register to set the host to high speed mode, and send CMD6 to switch the SD card to high speed mode ( $f_{pp} \leq 50\text{MHz}$ ). SDIOx\_CK can be set up to 50MHz after switch success.
- Step7.** When writing data, first send the multi-block write command CMD25. If using the CPU to write data, after confirming that the NORINTST.BWR bit is 1, write data to the data buffer register (BUF0, BUF1). During the sending process, BWR will keep 0, reset to 1 after sending, the user can write the data of the second block at this time. If using DMA to write data, wait for the DMA transfer to complete, SDIOC will send data through the data signal SDIOx\_Dy. The NORINTST.TC bit will be set to 1 and an interrupt request will be generated. If an error occurs in the transmission process, the corresponding error flag will be set and an interrupt request will be generated. After all the data is sent, if the automatic sending of CMD12 is set, SDIOC will automatically send a CMD12 to end the transmission, otherwise it is necessary to manually send CMD12 to the device to notify the device that the data transmission has ended.
- Step8.** When reading data, send the multi-block read command CMD18, and SDIOC will receive data through the data signal SDIOx\_Dy. If using the CPU to read data, after confirming that the NORINTST.BRR bit is 1, read the data from the data buffer register (BUF0, BUF1). The data of the second block can be read at this time. If using DMA to read data, wait for the DMA transfer to complete, after the reading is completed, the NORINTST.TC bit will be set to 1 and an interrupt request will be generated. If an error occurs during the transmission process, the corresponding error flag will be set and an interrupt will be generated. After all the data is received, if the automatic sending of CMD12 is set, the SDIOC will automatically send a CMD12 to end the transmission, otherwise it is necessary to manually send a CMD12 to the device to notify the device that the data transmission has ended.

#### 39.4.4 Transfer Abort, Suspend and Resume

When performing multi-block transfer, it can be aborted or suspended by software control. The abort operation can be performed regardless of whether or not the number of transfer data blocks is set. Abort operations are divided into asynchronous abort and synchronous abort. The asynchronous abort operation needs to send CMD12 to terminate the transmission by writing CMD register while the transmission is in progress, and the transmission will be terminated immediately at this time. For the write operation, the SD/MMC card will discard the current data block data and enter the program mode, and write the previously received data block into the FLASH. For read operations, SD/MMC will stop transferring data. Synchronous abort means that the transmission stops at the data block interval by setting the BLKGAP registe during the transmission. After the setting is completed, the transmission will stop after the current data block transmission ends. At this time, CMD12 needs to be sent to end the transmission.

When executing the suspend operation, first set the BLKGAP.SABGR bit to stop the transmission at the data block interval, and enable the read wait function. After the setting is complete, the transmission will stop transmission after the current data block transmission ends. At this time, send CMD52 by writing CMD register to suspend the transmission. After sending the suspend command, it is need to continue to read the CCCR.BS bit of SDIO through CMD52. If BS=0, it means that the transmission is suspended, and the SD bus turns to an idle state. After the transfer is suspended, the host can perform

operations on other functions of SDIO. But if you want to resume operation later, you need to back up the SDIOC register (offset address 0x00-0x0D) after suspending, and restore these register settings after performing other operations. When performing a resume operation, first clear the BLKGAP register to stop the transmission at the data block interval, and then send CMD52 to resume transmission by writing CMD register. After sending the recovery command, it is necessary to continue to read the CCCR.DF bit of SDIO through CMD52. If DF=1, it means that there is data to be transmitted after the recovery is executed. If DF=0, it means that there is no data to be transmitted. At this time, the data line should be reset by writing SFTRST register.

**Notice**

Suspend and resume operations require SDIO devices and combo card devices to support such operations and read wait operation. Access to the CIA area (common I/O area) of SDIO does not support suspend and resume operations, and only the read wait function can be used.

### 39.4.5 Read Wait

Read wait operation allows the host to insert CMD52 during continuous data transfers to access other functions of the SDIO device. When performing read wait, firstly, the transmission is stopped at the data block interval by setting the BLKGAP.SABGR bit, and the read wait operation is enabled. After the setting is completed, the host will pull the SDIOx\_D2 data line low after the current data block transmission is completed. The transmission will be suspended at this time, and the host can insert the CMD52 at this time to access other functions that do not require data transmission. When it is necessary to end the read wait operation, set the BLKGAP.CR bit and clear SABGR to resume transmission.

**Notice**

Read wait operation requires support from SDIO devices and combo card devices, and needs to be performed under four-wire bus transmission.

### 39.4.6 Wake-up

When not working for a long time, the system can be transferred to a low power consumption state to reduce power consumption. In the low power consumption state, the system can be woken up by SD/MMC/SDIO device insert/removal and card interrupt to continue working. When using the wake-up function, you need to enable the corresponding enable bit in NORINTSTEN register and NORINTSGEN register for insert/removal or card interrupt. At the same time, enable the corresponding wake-up function of the SDIOx\_CD/ SDIOx\_D1 port. After the configuration is complete, the system can be transferred to a low power consumption mode. When insert/removal and card interrupt, the wake-up function of the SDIOx\_CD/SDIOx\_D1 port will wake up the system and generate interrupts of insert/removal and card interrupt.

#### Use the Insert to Wake-up the Stop Mode Process

- Step1.** Configure the SDIOC port, select SDIOx\_CD as PA10.
- Step2.** Configure the PCR register of PA10, and select EIRQ10 to be active.
- Step3.** Configure the low power consumption mode of the power control module to stop mode. For configuration methods, please refer to the relevant description in the "Power Control (PWC)" chapter.
- Step4.** Configure the interrupt control module WUPEN register to enable the wake-up function of EIRQ10.

- Step5.** Configure the EIRQCR10 register of the interrupt control module and select the falling edge trigger.
- Step6.** Configure PWRCON to enable SDIOC.
- Step7.** Configure NORINTSTEN register and NORINTSGEN register to enable the corresponding enable bit of insert.
- Step8.** Configure the interrupt source selection register to select the SDIOC interrupt as the interrupt source and enable the interrupt.
- Step9.** Execute the WFI command to put the system into Stop mode.
- Step10.** When the device is plugged in, PA10 will be pulled low, wake up the CPU through EIRQ10, and enter the interrupt subroutine according to the SD interrupt request.
- Step11.** Clear the corresponding bit status of insert in NORINTST register, exit the interrupt subroutine, and perform subsequent operations.

#### Use the Insert to Wake-up the Power-down Mode Process

- Step1.** When the device is inserted, PA10 will be pulled low, and the system will be woken up through EIRQ10. Re-power on and configure the SDIOC port, and select SDIOx\_CD as PA10.
- Step2.** Configure the PWRC0 registers of the power control module to enable the CPU to enter the Power-down mode after executing the WFI command.
- Step3.** Configure the low power consumption mode of the power control module to Power-down mode. For configuration methods, please refer to the relevant description in the "Power Control (PWC)" chapter.
- Step4.** Configure the PDWKES register of the power control module and select the falling edge.
- Step5.** Execute the WFI command to put the system into Power-down mode.
- Step6.** When the device is plugged in, PA10 will be pulled low, wake up the system through WKUP2\_2 and power on again.

## 39.5 Register Description

The SDIOC module is designed according to the SD Host Controller Standard Specification, so the registers are the same as the standard description, and the unused addresses and bits are changed to reserved bits (Reserved).

### 39.5.1 Register List

SDIOC System Control Register base address: 0x40055400

Table 39-2 SDIOC System Control Register Offset

| Offset | Register                       | Description                   | Width |
|--------|--------------------------------|-------------------------------|-------|
| 0x04   | <a href="#">SDIOC_SYCTLREG</a> | SDIOC System Control Register | 32    |

- SDIOC1 base address: 0x40070000
- SDIOC2 base address: 0x40078400

Table 39-3 SDIO Controller (SDIOC) Register Offset

| Offset | Register                        | Description                | Width |
|--------|---------------------------------|----------------------------|-------|
| 0x04   | <a href="#">SDIOC_BLKSIZE</a>   | Data Block Size Register   | 16    |

### 39.5.2 Data Block Size Register (SDIOC\_BLKSIZE)

| Offset | Bit Position |    |    |    |     |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|-----|----|---|---|---|---|---|---|---|---|---|---|
| 0x04   | 15           | 14 | 13 | 12 | 11  | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x0000       |    |    |    |     |    |   |   |   |   |   |   |   |   |   |   |
| Name   | Reserved     |    |    |    | TBS |    |   |   |   |   |   |   |   |   |   |   |
| Access |              |    |    |    |     |    |   |   |   |   |   |   |   |   |   |   |
|        |              |    |    |    | RW  |    |   |   |   |   |   |   |   |   |   |   |

| Bit   | Name     | Function            | Description                                                                                  | Access |
|-------|----------|---------------------|----------------------------------------------------------------------------------------------|--------|
| 15:12 | Reserved | Reserved            | -                                                                                            | -      |
| 11:0  | TBS      | Transfer block size | Set the length of the data block to be transmitted, in bytes, with a value range of 1 to 512 | RW     |

### 39.5.3 Data Block Count Register (SDIOC\_BLKCNT)

| Offset | Bit Position |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| 0x06   | 15           | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x0000       |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | BC           |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Access | RW           |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| Bit  | Name | Function    | Description                                                                                                                                                        | Access |
|------|------|-------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 15:0 | BC   | Block Count | Set the number of transmission data blocks, set this register to be performed when the transmission is stopped, and the TRANSMODE.BCE bit is required to be active | RW     |

### 39.5.4 Argument Register 0 (SDIOC\_ARG0)

| Offset | Bit Position |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| 0x08   | 15           | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x0000       |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | ARG0         |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Access | RW           |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| Bit  | Name | Function         | Description                                                                                                   | Access |
|------|------|------------------|---------------------------------------------------------------------------------------------------------------|--------|
| 15:0 | ARG0 | Command argument | Set the argument contained in the current sending command, this register is the lower 16 bits of the argument | RW     |

### 39.5.5 Argument Register 1 (SDIOC\_ARG1)

| Offset | Bit Position |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| 0x0A   | 15           | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x0000       |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | ARG1         |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Access | RW           |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| Bit  | Name | Function         | Description                                                                                                   | Access |
|------|------|------------------|---------------------------------------------------------------------------------------------------------------|--------|
| 15:0 | ARG1 | Command argument | Set the argument contained in the current sending command, this register is the upper 16 bits of the argument | RW     |

### 39.5.6 Transmission Mode Register (SDIOC\_TRANSMODE)

| Offset | Bit Position |    |    |    |    |    |   |   |   |   |      |      |       |     |          |   |
|--------|--------------|----|----|----|----|----|---|---|---|---|------|------|-------|-----|----------|---|
| 0x0C   | 15           | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5    | 4    | 3     | 2   | 1        | 0 |
| Reset  | 0x0000       |    |    |    |    |    |   |   |   |   |      |      |       |     |          |   |

## 40 External Memory Controller (EXMC)

### 40.1 Introduction

The External Memory Controller (EXMC) is an independent block used to access various off-chip storage and achieve data exchange. Through configuration, EXMC can convert the internal AMBA protocol interface into various types of dedicated off-chip memory communication protocol interfaces, including SRAM, PSRAM, NOR Flash, NAND Flash, and SDRAM. EXMC is internally divided into multiple blocks, each supporting specific memory types. Users can control external corresponding memory types by configuring the registers of the block.

### 40.2 Features

Supported features are as follows:

- Supported external memory types: SRAM, PSRAM, NOR Flash, NAND Flash, SDRAM
- Interface protocol: Supports AHB protocol conversion with various external storage.
- Interface timing: Programmable interface timing for various memory types.
- Bus bit width:
  - ▶ SMC supports 8-bit, 16-bit, and 32-bit MEM bus width.
  - ▶ DMC supports 16-bit and 32-bit MEM bus width.
  - ▶ NFC supports 8-bit and 16-bit MEM bus width.
- Bus multiplexing: NOR Flash, and PSRAM support address line and data line multiplexing.
- Automatic splitting: When AHB bus bit width and external memory bit width do not match, automatic splitting and byte selection control are supported.
- Interrupt Type:
  - ▶ NFC ECC calculation completion interrupt
  - ▶ NFC ECC error interrupt
  - ▶ NFC device access end interrupt.

## 40.3 Functional Description

### 40.3.1 Controller Architecture

Various types of external memory controllers independently generate corresponding protocol interfaces and send them to the port MUX logic. The port MUX logic shares the addresses, data, and control signals of various external storage on the same port before outputting them from the chip's port. In this case, the EXMC controller can only access one external device at a time. Alternatively, partial signals of various external storage can be shared to access different external devices simultaneously.

Figure 40-1 EXMC Architecture Diagram

#### Note

In the architecture diagram, the SRAM/PSRAM/NOR Flash controller is defined as SMC (Static Memory Controller), the SDRAM controller is defined as DMC (Dynamic Memory Controller), and the NAND Flash controller is defined as NFC (NAND Flash Memory Controller). Subsequent mentions of SMC, DMC, and NFC have the same meaning as their corresponding controllers.

### 40.3.2 Basic Access Specification

EXMC is the conversion interface between the AHB bus protocol and external memory protocols. During data transmission in SMC and DMC, the AHB data width and memory data width may differ. To ensure data transmission consistency, read and write accesses must comply with the following specifications:

1. If the AHB access width equals the memory width, data is accessed normally.
2. If the AHB access width is greater than the memory width, the AHB access is automatically split into several consecutive memory data width transmissions.
3. If the AHB access width is less than the memory width, the corresponding bytes are accessed through the byte selection control signals SMC\_BLS [3:0] or DMC\_DQM[3:0].

For specific access methods between AHB access width and storage of various data bit widths, refer to the table below.

Table 40-1 Table of AHB Access Width and Memory Bit Width Corresponding Access Methods

| RW | AHB Access Width | External Memory Width | Description                                  |
|----|------------------|-----------------------|----------------------------------------------|
| R  | 8                | 8                     | -                                            |
|    | 16               |                       | Converted into 2 EXMC read operations.       |
|    | 32               |                       | Converted into 4 EXMC read operations.       |
|    | 8                | 16                    | -                                            |
|    | 16               |                       | -                                            |
|    | 32               |                       | Converted into 2 EXMC read operations.       |
|    | 8                | 32                    | -                                            |
|    | 16               |                       | -                                            |
|    | 32               |                       | -                                            |
| W  | 8                | 8                     | Use byte control signal BLS[0]               |
|    | 16               |                       | Converted into 2 EXMC write operations.      |
|    | 32               |                       | Converted into 4 EXMC write operations.      |
|    | 8                | 16                    | Use Byte Control Signal BLS[1:0] or DQM[1:0] |
|    | 16               |                       | -                                            |
|    | 32               |                       | Converted into 2 EXMC write operations.      |
|    | 8                | 32                    | Use Byte Control Signal BLS[3:0] or DQM[3:0] |
|    | 16               |                       | Use Byte Control Signal BLS[3:0] or DQM[3:0] |
|    | 32               |                       | -                                            |

**Note**

The above table only applies data access SMC and DMC, where SMC supports external memory bit width of 8/16/32, and DMC supports external memory bit width of 16/32.

### 40.3.3 Address Mapping

This product defines a total of 1GB of external memory access space for data exchange between different types of external storage and internal data, including EXMC and QSPI. The 1GB space is allocated as shown in the figure below: SRAM/PSRAM/NOR Flash (SMC) data access maps to a 512MB address space, SDRAM (DMC) data access maps to a 128MB address space, NAND Flash (NFC) control and data access maps to a 1MB address space, and QSPI control and data access maps to a 128MB address space.

Figure 40-2 External Address Space Allocation

#### Note

1. Access control for the address space 0x98000000-0x9FFFFFFF is implemented by the QSPI block. For details, refer to the relevant description in the "Quad Serial Peripheral Interface (QSPI)" chapter.
2. The DMC data address space 0x80000000-0x87FFFFFFF does not have bufferable functionality. To improve DMC write efficiency, use the ARM Cortex-M4 built-in MPU to set this address range as bufferable.

### SMC Address Space

The SMC address space can be divided into 4 programmable-sized Chips. The space size of each Chip can be divided by setting the chip select control register (SMC\_CSCR0-1). The external memory objects corresponding to each Chip can be independently configured and correspond to different CS (Chip Select) signals output to external ports. The figure below shows the SMC Chip Select division. When the CPU accesses the address space within an SMC CS space, the corresponding SMC\_CS signal output becomes active.

Figure 40-3 SMC Address Space Partitioning

**Note**

For the SMC address setting method, refer to "[Chip Select Control Register \(SMC\\_CSCR1\)](#)".

**DMC Address Space**

The DMC address space can be divided into 4 programmable-sized Chips. The space size of each Chip can be divided by setting the chip select control register (DMC\_CSCR0-3). The external memory objects corresponding to each Chip can be independently configured and correspond to different CS (Chip Select) signals output to external ports. The figure below shows the DMC Chip Select division. When the CPU accesses the address space within a DMC CS space, the corresponding DMC\_CS signal output becomes active.

Figure 40-4 DMC Address Space Division

**Note**

For the DMC address setting method, refer to "[Chip Select Control Register \(DMC\\_CSCR0-3\)](#)".

## NFC Address Space

The NFC address space is divided into data register space and control register space. The data register occupies 32KB space, and the control register occupies 32KB space, totaling 64KB. The remaining addresses are reserved for NFC. The figure below shows the NFC address space division.

Figure 40-5 NFC Address Space Division

## 40.3.4 Protocol Interface

SMC, DMC, and NFC correspond to different types of storage, each with different types of protocol interface signals. EXMC achieves data exchange with external storage through this interface protocol. The following describes the protocol interfaces required for various types of storage.

### SMC Protocol Interface

The table below lists the protocol interfaces required for SRAM/PSRAM/NOR Flash control (SMC) access.

Table 40-2 SMC Protocol Interface

| Protocol Interface Name | Direction    | Active level.        | Description                        |
|-------------------------|--------------|----------------------|------------------------------------|
| SMC_CLK                 | Output       | High level/low level | SMC Clock Output                   |
| SMC_ADD[28:0]           | Output       | High level/low level | SMC address output                 |
| SMC_DATA[31:0]          | Input/Output | High level/low level | SMC Data                           |
| SMC_WE                  | Output       | Low level            | SMC write enable                   |
| SMC_OE                  | Output       | Low level            | SMC output enable                  |
| SMC_CS[3:0]             | Output       | Low level            | SMC chip select signal             |
| SMC_BLS[3:0]            | Output       | Low level            | SMC byte strobe signal             |
| SMC_ADV                 | Output       | Low level            | SMC address latch signal           |
| SMC_CRE                 | Output       | High level           | SMC's MdRegConfig indicates signal |

| Protocol Interface Name | Direction | Active level. | Description           |
|-------------------------|-----------|---------------|-----------------------|
| SMC_WAIT                | Input     | Low level     | SMC input wait signal |

### DMC Protocol Interface

The table below lists the protocol interfaces required for SDRAM control (DMC) access.

Table 40-3 DMC Protocol Interface

| Protocol Interface Name | Direction    | Active level. | Description                                                |
|-------------------------|--------------|---------------|------------------------------------------------------------|
| DMC_CLK                 | Output       | -             | DMC's clock output.                                        |
| DMC_ADD[13:0]           | Output       | -             | DMC's address output.                                      |
| DMC_DATA[31:0]          | Input/Output | -             | DMC's data.                                                |
| DMC_CKE                 | Output       | High level    | DMC's CLK output enable.                                   |
| DMC_AP                  | Output       | High level    | DMC's Auto Precharge command indication signal (optional). |
| DMC_WE                  | Output       | Low level     | DMC's write enable.                                        |
| DMC_RAS                 | Output       | Low level     | DMC's row address strobe signal.                           |
| DMC_CAS                 | Output       | Low level     | DMC's column address strobe signal.                        |
| DMC_BA[1:0]             | Output       | -             | DMC's Bank address signal.                                 |
| DMC_CS[3:0]             | Output       | Low level     | DMC's chip select signal.                                  |
| DMC_DQM[3:0]            | Output       | Low level     | DMC's byte strobe signal.                                  |

### NFC Protocol Interface

The table below lists the protocol interfaces required for NAND Flash control (NFC) access.

Table 40-4 NFC Protocol Interface

| Protocol Interface Name | Direction    | Active level. | Description                 |
|-------------------------|--------------|---------------|-----------------------------|
| NFC_CLE                 | Output       | High level    | NFC Command Lock Signal     |
| NFC_ALE                 | Output       | High level    | NFC Address Lock Signal     |
| NFC_DATA[15:0]          | Input/Output | -             | NFC Address and Data        |
| NFC_CE[7:0]             | Output       | Low level     | NFC's Chip Select Signal    |
| NFC_WE                  | Output       | Low level     | NFC's Write Enable          |
| NFC_RE                  | Output       | Low level     | NFC Read Enable             |
| NFC_WP                  | Output       | Low level     | NFC Write Protection Signal |
| NFC_RB[7:0]             | Input        | Low level     | NFC Input Busy Signal       |

### EXMC Port Function Configuration

Based on the interface signal tables of the above three types of external storage, the EXMC port function configuration is divided into two types: accessing one external device at a time and accessing multiple external devices simultaneously.

For port function configuration when accessing one external device at a time, refer to the table below.

**Table 40-5 EXMC Port Function Mapping 1**

| Pin Name                   | Direction        | Active Level.        | Description     |                 |                |
|----------------------------|------------------|----------------------|-----------------|-----------------|----------------|
|                            |                  |                      | SMC             | DMC             | NFC            |
| EXMC_CLK                   | Output           | High level/low level | SMC_CLK         | DMC_CLK         | -              |
| EXMC_ADD28-18              | Output           | High level/low level | SMC_ADD[28:18]  | -               | -              |
| EXMC_ADD17_DMC_BA1_NFC_ALE | Output           | High level/low level | SMC_ADD[17]     | DMC_BA[1]       | -              |
| EXMC_ADD16_DMC_BA0_NFC_CLE | Output           | High level/low level | SMC_ADD[16]     | DMC_BA[0]       | -              |
| EXMC_ADD15                 | Output           | High level/low level | SMC_ADD[15]     | -               | -              |
| EXMC_ADD14                 | Output           | High level/low level | SMC_ADD[14]     | -               | -              |
| EXMC_ADD13-0               | Output           | High level/low level | SMC_ADD[15:0]   | DMC_ADD[13:0]   | -              |
| EXMC_DATA31-0              | Input/<br>Output | High level/low level | SMC_DATA[31:16] | DMC_DATA[31:16] | -              |
|                            | Input/<br>Output | High level/low level | SMC_DATA[15:0]  | DMC_DATA[15:0]  | NFC_DATA[15:0] |
| EXMC_WE                    | Output           | Low level            | SMC_WE          | DMC_WE          | NFC_WE         |
| EXMC_CE7-4                 | Output           | Low level            | SMC_BLS[3:0]    | DMC_DQM[3:0]    | NFC_CE[7:4]    |
| EXMC_CE3-0                 | Output           | Low level            | SMC_CS[3:0]     | DMC_CS[3:0]     | NFC_CE[3:0]    |
| EXMC_OE                    | Output           | Low level            | SMC_OE          | DMC_RAS         | NFC_RE         |
| EXMC_BAA                   | Output           | Low level            | -               | DMC_CAS         | NFC_WP         |
| EXMC_ADV                   | Output           | Low level            | SMC_ADV         | -               | -              |
| EXMC_ALE                   | Output           | High level           | SMC_CRE         | DMC_CKE         | NFC_ALE        |
| EXMC_CLE                   | Output           | High level           | -               | DMC_AP          | NFC_CLE        |
| EXMC_RB7-1                 | Input            | Low level            | -               | -               | NFC_RB[7:1]    |
| EXMC_RB0                   | Input            | Low level            | SMC_WAIT        | -               | NFC_RB[0]      |

The function configuration for accessing multiple external devices simultaneously is shown in the table below. This configuration can also be used for accessing one external device at a time.

**Note**

1. NFC does not support simultaneous use with either or both SMC/DMC.
2. Direct data transfer between DMC and SMC via the CPU is disabled. If data transfer between SMC and DMC is required, use DMA transfer or relay transfer through system RAM.

**Table 40-6 EXMC Port Function Mapping 2**

| Pin Name           | Direction | Active Level.        | Description    |           |         |
|--------------------|-----------|----------------------|----------------|-----------|---------|
|                    |           |                      | SMC            | DMC       | NFC     |
| EXMC_DMC_CLK       | Output    | High level/low level | -              | DMC_CLK   | -       |
| EXMC_SMC_CLK       | Output    | High level/low level | SMC_CLK        | -         | -       |
| EXMC_ADD28-18      | Output    | High level/low level | SMC_ADD[28:18] | -         | -       |
| EXMC_ADD17_NFC_ALE | Output    | High level/low level | SMC_ADD[17]    | -         | NFC_ALE |
| EXMC_ADD16_NFC_CLE | Output    | High level/low level | SMC_ADD[16]    | -         | NFC_CLE |
| EXMC_ADD15_DMC_BA1 | Output    | High level/low level | SMC_ADD[15]    | DMC_BA[1] | -       |
| EXMC_ADD14_DMC_BA0 | Output    | High level/low level | SMC_ADD[14]    | DMC_BA[0] | -       |

| Pin Name            | Direction        | Active Level.        | Description     |                 |                |
|---------------------|------------------|----------------------|-----------------|-----------------|----------------|
|                     |                  |                      | SMC             | DMC             | NFC            |
| EXMC_ADD13-0        | Output           | High level/low level | SMC_ADD[13:0]   | DMC_ADD[13:0]   | -              |
| EXMC_DATA31-0       | Input/<br>Output | High level/low level | SMC_DATA[31:16] | DMC_DATA[31:16] | -              |
|                     | Input/<br>Output | High level/low level | SMC_DATA[15:0]  | DMC_DATA[15:0]  | NFC_DATA[15:0] |

| EXMC_DMC_CS3-0      | Output           | Low level            | -               | DMC_CS[3:0]     | -              |
| EXMC_NFC_CE7-4      | Output           | Low level            | -               | -               | NFC_CE[7:4]    |
| EXMC_DMC_RAS        | Output           | Low level            | -               | DMC_RAS         | -              |
| EXMC_SMC_BAA_NFC_WP | Output           | Low level            | -               | -               | NFC_WP         |
| EXMC_DMC_CAS        | Output           | Low level            | -               | DMC_CAS         | -              |
| EXMC_SMC_ADV        | Output           | Low level            | SMC_ADV         | -               | -              |
| EXMC_DMC_CKE        | Output           | High level           | -               | DMC_CKE         | -              |
| EXMC_SMC_CRE        | Output           | High level           | SMC_CRE         | -               | -              |
| EXMC_DMC_AP         | Output           | High level           | -               | DMC_AP          | -              |
| EXMC_RB7-1          | Input            | Low level            | -               | -               | NFC_RB[7:1]    |
| EXMC_RB0            | Input            | Low level            | SMC_WAIT        | -               | NFC_RB[0]      |

### 40.3.5 SMC-SRAM/PSRAM/NOR Flash Controller

#### 40.3.5.1 SRAM/PSRAM/NOR Flash Introduction

SRAM/NOR Flash are storage with static access functionality that can retain internally stored data without a refresh circuit. The width of the address lines determines the number of storage units. Each storage unit corresponds to a space of the memory storage width for storing data. Therefore, the capacity of SRAM/PSRAM/NOR Flash storage is memory data width x  $2^{\text{address line width}}$ .

PSRAM is pseudo-static RAM. Because it has an SRAM interface, it can exchange data with the system internally through the SMC block of EXMC, just like SRAM.

#### 40.3.5.2 SMC Basic Functions

The basic functions and features of SMC are as follows:

- Supports 8-bit, 16-bit and 32-bit external memory data bandwidth.
- AHB word, half-word, and byte access.
- Provides independent chip select control for each memory Chip.
- Byte selection signal output.
- Address line and data line multiplexing.
- Programmable protocol timing parameters.
- Programmable-rate automatic refresh action (used for PSRAM).
- 2 command FIFOs.

- Equipped with four 32-bit write data FIFOs
- Equipped with four 32-bit read data FIFOs.
- Low power management.
- Supports LCD parallel interface, compatible with 8080/6800 modes.

#### 40.3.5.3 SMC Initial Setting

The state diagram and transitions between states of SMC after power on reset are shown below.

During initial reset, SMC is in the Low Power state. By setting the state control register (SMC\_STCR0 and SMC\_STCR1), SMC can switch between the Ready state and the Low Power state. For details, refer to "[SMC Low Power Management](#)".

Figure 40-6 SMC State Diagram

Before communicating with external SRAM, PSRAM, NOR Flash, etc., SMC must be initially set up and the relevant parameters configured to ensure correct data transmission. For the specific setup sequence, refer to the figure below.

Figure 40-7 SMC Initial Setup Process

#### 40.3.5.4 SMC Access Actions

##### 40.3.5.4.1 Access Method

For SMC's read and write operations on external storage, either synchronous or asynchronous access modes can be selected.

Synchronous access mode corresponds to synchronous-access-type external storage. When SMC outputs read and write control signals, the clock signal is also output simultaneously. The external memory performs data transmission with SMC based on the clock output by SMC, i.e., SMC\_CLK is active. Asynchronous access mode corresponds to asynchronous-access-type external storage. When SMC outputs read and write control signals, the clock signal is not output (output remains low). The external memory achieves data access based on other control signals.

In synchronous access mode, the read and write action between SMC and external memory is controlled by the SMC\_WAIT signal. When the SMC\_WAIT signal input is at a low level, SMC is in a wait state and does not perform any operations. SMC resumes normal read and write access only after SMC\_WAIT becomes high level.

By setting the SMC\_CPCR.RSYN and SMC\_CPCR.WSYN bits, synchronous or asynchronous read and write modes can be selected.

#### Note

If no pin is configured as the EXMC\_RB0 function (see "Pin Definitions - Pin Function Description" in the "Datasheet"), the read and write action of SMC is not controlled by the SMC\_WAIT signal.

#### 40.3.5.4.2 Access Timing

SMC supports access to multiple types of storage and can convert AHB single or burst read and write operations into memory read and write operations. Below are examples of timing sequences for data read and write operations between the controller and external memory:

1. [Single Read Action](#)
2. [Single Read Action with Address and Data Line Multiplexing](#)
3. [Single Write Operation](#)
4. [Single Write Action with Address and Data Line Multiplexing in Asynchronous Mode](#)
5. [Single Write Action with Address and Data Line Multiplexing in Synchronous Mode](#)

#### Single Read Action

The basic timing diagram and setup example for a single read action are as follows:

**Table 40-7 Basic Setup Example for a Single Read Action**

|                  |        |       |        |      |       |       |                                                                   |
|------------------|--------|-------|--------|------|-------|-------|-------------------------------------------------------------------|
| Basic set-tings  | MW     | RSYN  | WSYN   | -    | ADVS  | BLSS  | - indicates not appli-cable.<br><set> indi-cates user-set values. |

### Single Write Action with Address and Data Line Multiplexing in Synchronous Mode

The basic timing diagram and setup example for a single write action with address and data line multiplexing in synchronous mode are as follows:

**Table 40-11 Basic Setup Example for a Single Write Action with Address and Data Line Multiplexing in Synchronous Mode**

|                      |       |        |        |       |       |       |                                                                         |
|----------------------|-------|--------|--------|-------|-------|-------|-------------------------------------------------------------------------|
| Basic set-<br>tings  | MW    | RSYN   | WSYN   | -     | ADVS  | BLSS  | - indicates<br>not appli-<br>cable.<br>indicates<br>user-set<br>values. |
|                      | <set> | -      | 1      | -     | 0b1   | 0b1   |                                                                         |
| Timing set-<br>tings | T_RC  | T_WC   | T_CEOE | T_WP  | T_TR  | T_ADV |                                                                         |
|                      | -     | 0b0101 | -      | 0b011 | 0b010 | 0b001 |                                                                         |

**Figure 40-24 Basic Timing for Single Write Action with Address and Data Line Multiplexing (Synchronous Mode (WSYN=0b1) & 16-bit Width (MW=0b01) )**

#### 40.3.5.4.3 FIFO Management

SMC contains 3 types of FIFOs. These are command FIFOs, write data FIFOs, and read data FIFOs.

- Command FIFO: 2 command FIFOs for buffering 2 SMC commands and their corresponding command addresses, CS, etc.
- Write data FIFO: 4 write data FIFOs for buffering AHB write data.
- Read data FIFO: 4 read data FIFOs for buffering data read from SRAM/PSRAM/NOR Flash.

#### 40.3.5.5 SMC Low Power Management

When SMC is in Low Power state, if the LPWOR bit of the state control register (SMC\_STCR1) is set to 1, SMC transitions from the Low Power state to the Ready state and starts normal operation. If there is no operation on SMC for a long time, the LPWIR bit of the state control register (SMC\_STCR0) can be set to 1 to put SMC into the Low Power state. After entering the Low Power state, SMC's internal actions stop, and power consumption decreases.

### 40.3.6 DMC-SDRAM Controller

#### 40.3.6.1 SDRAM Introduction

Synchronous Dynamic Random Access Memory (SDRAM) is a type of DRAM refreshed based on an external synchronous clock. Its synchronous clock is provided by the DMC\_CLK pin of DMC.

#### Bank Characteristics

SDRAM can be internally divided into multiple Banks (EXMC supports storage with up to 4 Banks), allowing devices to access them in an interleaved manner for greater concurrency and data transfer capacity. Each Bank is a memory matrix composed of rows and columns. The selection of rows and columns locates a storage unit, which corresponds to a space of the memory storage width. Therefore, the size of each Bank in SDRAM can be considered as memory data width x number of rows x number of columns. Users can match the parameters of DMC and external SDRAM by setting the relevant parameters (row address length, column address length, etc.) in the chip select control register (DMC\_CSCR), enabling communication with different SDRAMs.

#### Row Activation

Row activation enables the Bank where the row address is located. The complete row address consists of a 2-Bit Bank address (DMC\_BA[1:0]) and a 16-Bit row address (DMC\_ADD[15:0]). Row activation reads all bit information of the selected row into the read and write amplifier. Once row activation is complete, read and write operations can proceed smoothly.

Row activation requires a certain amount of time, called the row-to-column delay, which is the minimum time interval between row addressing and column addressing. The row-to-column delay ( $T_{RCD}$ ) of DMC is the minimum number of clock periods that includes the SDRAM row-to-column delay. It represents the minimum wait time from row enable to SDRAM read and write. This time can be set via the timing configuration register (DMC\_TMCR\_T\_RCD). During this time, since the SDRAM controller operates on Banks independently, users can issue control commands to other Bank addresses. The figure below shows the timing diagram from row activation to read and write operations.

Figure 40-25 Timing from Row Activation to Read and Write Operations

**Note**

Row activation is represented as "Active" in the timing diagrams of the EXMC chapter.

**Precharge**

If DMC needs to perform row switching when accessing external data, the originally active (working) row of the Bank must be closed, and the row and column addresses must be resent. The operation of closing the current working row of a Bank and preparing to open a new row is called precharging. The precharge action can be triggered by the precharge command (PrechargeAll) in the command register (DMC\_CMDR) or during read and write row switching.

In burst read or burst write commands, the A10/A8 bit (set by DMC\_CPCR.APBS) becomes "H", and a precharge action is automatically appended after the read and write operation is completed, achieving auto-precharge.

The row precharge delay ( $T_{RP}$ ) represents the minimum time for SDRAM row switching. It is the minimum time interval from precharge completion to the next execution of enable command. This time can be set via the timing configuration register (DMC\_TMCR\_T\_RP). Below are timing diagrams for two different precharge methods.

Figure 40-26 Command-based Precharge

Figure 40-27 Auto-precharge after Read and Write

**Refresh Action**

Due to leakage in the storage cells of dynamic memory, periodic refreshing of all storage cells is necessary to maintain data correctness. EXMC supports two refresh methods: Auto Refresh (AR) and Self Refresh (SR).

Auto Refresh (AR) involves EXMC periodically issuing refresh commands. The refresh interval is determined by the refresh time register (DMC\_RFTR). The refresh targets all Banks (corresponding rows of all Banks are refreshed simultaneously), and auto-refresh operations are initiated only when all Banks are idle and not in a low power state. During auto-refresh execution, only no-operation commands can be input. Other commands must wait and cannot be executed. After auto-refresh execution completes, all Banks enter the idle state.

Self Refresh (SR) is mainly used for data storage in low power states during Sleep mode. When DMC\_CKE is inactive during an AR command, the self-refresh mode is entered. During SR, SDRAM no longer relies on the DMC\_CLK clock but performs refresh operations based on its internal clock. During SR, all

external signals except DMC\_CKE are inactive (no external refresh commands are required). When DMC transitions from the Pause state to the Low Power state (by issuing a Sleep command), it automatically issues a self-refresh command. The figure below shows the timing diagram for entering and exiting the self-refresh action.

Figure 40-28 Timing for Entering and Exiting the Self-refresh Action

### Command Truth Table

Various commands for controlling and accessing SDRAM are issued by the SDRAM protocol interface of DMC. The specific command list is shown in the table below.

Table 40-12 DMC Command Truth Table

| DMC_CS | DMC_RAS | DMC_CAS | DMC_WE | DMC_BA | DMC_ADD |             | Command                                |
|--------|---------|---------|--------|--------|---------|-------------|----------------------------------------|
|        |         |         |        |        | ADD[xx] | ADD[10]/[8] |                                        |
| 0      | 0       | 0       | 0      | 0      | Config  |             | MdRegConfig Command                    |
| 0      | 0       | 0       | 1      | -      | -       | -           | SelfRefresh command (DMC_CKE=0).       |
|        |         |         |        |        |         |             | AutoRefresh Command (DMC_CKE=1)        |
| 0      | 0       | 1       | 0      | -      | -       | 1           | PrechargeAll Command                   |
|        |         |         |        | Bank   | -       | 0           | Precharge command for a specified Bank |
| 0      | 0       | 1       | 1      | Bank   | Row     | Row         | Row activation command                 |
| 0      | 1       | 0       | 0      | Bank   | Col     | 1           | Precharge command during write action  |
|        |         |         |        | Bank   | Col     | 0           | Write operation command                |
| 0      | 1       | 0       | 1      | Bank   | Col     | 1           | Precharge command during read action   |
|        |         |         |        | Bank   | Col     | 0           | Read operation command                 |
| 0      | 1       | 1       | 0      | -      | -       | -           | Abort burst transfer                   |
| 0      | 1       | 1       | 1      | -      | -       | -           | No operation                           |
| 1      | -       | -       | -      | -      | -       | -           | Command Inhibit                        |

### 40.3.6.2 DMC Basic Functions

The basic functions and features of DMC are as follows:

- Supports 16-bit and 32-bit external memory data bandwidth.
- Supports up to 16-bit row addresses, 12-bit column addresses, and 2-bit internal Bank addresses.
- AHB word, half-word, and byte access.
- Provides independent chip select control for each memory Chip.
- The size of each memory Chip can be independently configured.
- Byte selection signal output.
- Automatic row and Bank boundary management.

- Programmable protocol timing parameters.
- Programmable-rate auto-refresh action.
- With 2 41-bit command FIFOs.
- With 10 36-bit write data FIFOs
- With 10 32-bit read data FIFOs.
- Low power management.

#### 40.3.6.3 DMC Initial Setting

The state diagram and transitions between states of DMC after Power On Reset are shown below.

During initial reset, DMC enters the Config state. If a Go command is issued via the state control register (DMC\_STCR) and no operations follow, DMC automatically enters the Low Power state. During normal action, state transitions of DMC can be controlled by settings in the state control register (DMC\_STCR). For details, refer to "[DMC Low Power Management](#)".

Figure 40-29 DMC State Diagram

Before communicating with external SDRAM, DMC must be initially set up and the relevant parameters configured to ensure correct data exchange. For the specific setup sequence, refer to the figure below.

Figure 40-30 DMC Initial Setup Process

#### 40.3.6.4 DMC Access Actions

##### 40.3.6.4.1 Access Timing

DMC can convert AHB single or burst read and write operations into memory read and write operations. The following are methods for data read and write operations with external SDRAM:

1. [Single Read Action](#)
2. [Single Write Action](#)
3. [Burst Read Action](#)
4. [Burst Write Action](#)

##### Single Read Action

The figure below shows the basic timing diagram for a single read action.

In the figure, `cas_latency` is the delay from the read command to data readout (the DMC block reads data on the rising edge of `DMC_CLK`). This can be set via the timing configuration register (`DMC_TMCR_T_CASL`).

Figure 40-31 Basic Timing for Single Read Action (16-bit Width (DMCMW=0b00) )

## Single Write Action

The figure below shows the basic timing diagram for a single write action.

In the figure,  $t_{dqss}$  is the delay between write enable and write data. This can be configured via the timing configuration register (DMC\_TMCR\_T\_DQSS).

Figure 40-32 Basic Timing for Single Write Action (32-bit Width (DMCMW=0b01) )

### Burst Read Action

The figure below shows the basic timing diagram for a burst read action.

Figure 40-33 Basic Timing for Burst Read Action (32-bit Width (DMCMW=0b10) & BURST=0b010)

### Burst Write Action

The figure below shows the basic timing diagram for a burst write action.

Figure 40-34 Basic Timing for Burst Write Action (32-bit Width (DMCMW=0b10) & BURST=0b011)

#### 40.3.6.4.2 FIFO Management

DMC contains 3 types of FIFOs. These are command FIFOs, write data FIFOs, and read data FIFOs.

**Command FIFO:** 2 command FIFOs for buffering 2 DMC commands and their corresponding command addresses, CS, etc.

**Write data FIFO:** 10 write data FIFOs for buffering AHB write data.

**Read data FIFO:** 10 read data FIFOs for buffering data read from SDRAM.

### 40.3.6.5 DMC Low Power Management

DMC can switch between the Ready state and the Low Power state internally to manage power consumption. It can also control the DMC output clock or clock enable during idle states to manage the power consumption of external SDRAM.

#### Low Power State Control

When DMC is in the Config state, issuing Go, Pause, and Sleep commands in sequence via the state control register (DMC\_STCR) puts DMC into the Low Power state. After entering the Low Power state, DMC's internal actions stop, and power consumption decreases. In the Low Power state, issuing Wakeup and Go commands in sequence via the state control register (DMC\_STCR) causes DMC to exit the Low Power state and enter the Ready state, starting normal action.

#### DMC\_CLK Output Control

When the CKSTOP bit of the CHIP configuration register (DMC\_CPCR) is set to 1, the clock output of the DMC\_CLK port automatically stops when DMC is not operating on external SDRAM. When a new operation occurs, the DMC\_CLK clock restarts. After the action completes, DMC\_CLK stops again automatically, achieving control over the DMC\_CLK clock output during idle states and thereby controlling the power consumption of DMC and SDRAM.

#### DMC\_CKE Output Control

When the CKEDIS bit of the CHIP configuration register (DMC\_CPCR) is set to 1, after DMC performs an operation on external SDRAM and the period set by DMC\_CPCR.CKEDISPRD[5:0] elapses, DMC becomes idle, and the port output of DMC\_CKE becomes inactive. When a new operation occurs, DMC\_CKE becomes active again. After the action completes, DMC\_CKE becomes inactive again, achieving control over the clock output enable DMC\_CKE during idle states and thereby controlling the power consumption of SDRAM. The following figure shows the timing diagram for DMC\_CKE port output control.

Figure 40-35 DMC\_CKE Port Output Control Timing

## 40.3.7 NFC-NAND Flash Controller

### 40.3.7.1 Introduction to NAND Flash

NAND Flash memory is a type of Flash memory that uses a nonlinear macrocell mode internally, providing a cost-active solution for solid-state high-capacity memory. NAND Flash memory has advantages such as large capacity and fast rewrite speeds, making it suitable for storing large amounts of data. It is increasingly widely used in industries, such as in embedded products like digital cameras, MP3 player memory cards, and compact USB drives.

### 40.3.7.2 NFC Basic Functions

The basic functions and features of NFC are as follows:

- Supports the ONFI protocol, enabling simple access to SLC and MLC NAND Flash devices.
- Supports devices with page sizes of 2KB/4KB/8KB.
- Supports devices with 8-bit and 16-bit bit width.
- Supports 1-bit Hamming code ECC correction per 512Byte unit.
- Can calculate 4-bit BCH code per 512Byte unit and provide the syndrome when an ECC error occurs.
- Access timing can be configured via registers

### 40.3.7.3 NFC Access Commands

The table below lists the ONFI access commands supported by NFC. "Mandatory" indicates commands that all ONFI devices must support. "Optional" indicates commands that some ONFI devices may support.

Table 40-13 ONFI Access Commands

| Command                      | Mandatory (M) / Optional (O). | First Period (Command). | Second Period (Confirm). |
|------------------------------|-------------------------------|-------------------------|--------------------------|
| Read                         | M                             | 0x00                    | 0x30                     |
| Copyback read                | O                             | 0x00                    | 0x35                     |
| Change read column           | M                             | 0x05                    | 0xE0                     |

#### 40.3.7.4 NFC Access Actions

##### Page Read

- Step1.** Write 0x00000000 to the command register.
- Step2.** Write the NAND Flash address to the index register.
- Step3.** Write 0x000000E0 to the command register or perform a read operation on the data register. At this time, the NAND Flash device pulls the RB signal low, indicating that the device is preparing data. When the RB signal returns to high, it indicates that the data is ready. Therefore, if the method of writing 0x000000E0 to the command register is used, wait until the RB signal is high before reading the data register. If a read operation is performed on the data register, the controller inserts a wait on the bus until RB is high and return the first data.
- Step4.** Read the entire page of data by reading the data register.
- Step5.** The user does not need to read all the data of the page. After reading the required data, write 0x00000023 to the command register. The controller automatically reads the remaining data and starts calculating ECC. When the ECC calculation is completed, an interrupt is generated, and the flag bit is set. The ECC result is written to the ECC result register. If the user selects ECC function inactive, this step is omitted.
- Step6.** Write 0x000000FE to the command register to end the current read operation and set CE to inactive.

##### Page Write

- Step1.** Write 0x00000080 to the command register.
- Step2.** Write the NAND Flash address to the index register.
- Step3.** Write data to the data register in sequence. When ECC is active, the controller calculates ECC while writing data.
- Step4.** After writing all the data, write 0x00000010 to the command register, and the NAND Flash device will start programming while pulling RB low. When ECC is enabled, if the data written by the user is less than 1 page, the controller will automatically fill the remaining address with FF and calculate the ECC value. (When ECCM is in 1-bit ECC mode: the ECC value is automatically written to the spare area of the NAND Flash device after writing the data; when ECCM is in 4-bit ECC mode: an 8-byte ECC value is written after every 512 bytes);
- Step5.** After programming is completed, the NAND Flash device restores RB to high. Write 0x000000FE to the command register to end the write operation and set CE to inactive.

### Block Erase

- Step1.** Write 0x81000M60 to the command register, where M is the BANK number;
- Step2.** Write 0x40000MAB to the command register, where M is the BANK number and AB is the least significant byte of the NAND Flash row address.
- Step3.** Write 0x40000MWX to the command register, where M is the BANK number and WX is the second lowest byte of the NAND Flash row address.
- Step4.** Write 0x40000MYZ to the command register, where M is the BANK number and YZ is the highest byte of the NAND Flash row address.
- Step5.** Write 0x00000MD0 to the command register, where M is the BANK number;
- Step6.** Wait for the NAND Flash device to restore RB to high.

### Reset

- Step1.** Write 0x00000MFF to the command register, where M is the BANK number;
- Step2.** Wait for the NAND Flash device to restore RB to high.

### Read ID

- Step1.** Read the data register once;
- Step2.** Write 0x81000M90 to the command register, where M is the BANK number;
- Step3.** Write 0x40000MAB to the command register, where M is the BANK number and AB is the address of the ID.
- Step4.** Read the data register to get the ID;
- Step5.** Writing 0x000000FE to the command register deasserts CE.

### Read Status

- Step1.** Write 0x81000M70 to the command register, where M is the BANK number;
- Step2.** Read the data register, the lowest byte of the register value is the status value;
- Step3.** Writing 0x000000FE to the command register deasserts CE.

## 40.3.8 Interrupt Description

NFC has three types of interrupt events. The interrupt enable register (NFC\_IENR) controls whether the corresponding interrupt occurs. The user can determine whether an interrupt event occurs by querying the interrupt status register (NFC\_ISTR) and clear the interrupt event by writing the register. The three types of NFC interrupt events are as follows:

1. An interrupt occurs when the ECC calculation is completed
2. Interrupt when ECC check error occurs
3. Each RB signal generates a rising edge, that is, an interrupt occurs when the corresponding device is ready

## 40.4 Register Description

### 40.4.1 Register List

EXMC common register base address: 0x40055400

Table 40-14 EXMC Common Register Offset

| Offset | Register  | Description          | Width |

## 40.4.3.7 Chip Select Control Register (SMC\_CSCR1)

| Offset | Bit Position |    |    |    |    |    |    |    |         |    |    |    |    |    |    |    |         |    |    |    |    |    |   |   |         |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|---------|----|----|----|----|----|----|----|---------|----|----|----|----|----|---|---|---------|---|---|---|---|---|---|---|
| 0x020C | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23      | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15      | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7       | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x00000000   |    |    |    |    |    |    |    |         |    |    |    |    |    |    |    |         |    |    |    |    |    |   |   |         |   |   |   |   |   |   |   |
| Name   | ADDMAT3      |    |    |    |    |    |    |    | ADDMAT2 |    |    |    |    |    |    |    | ADDMAT1 |    |    |    |    |    |   |   | ADDMAT0 |   |   |   |   |   |   |   |
| Access | RW           |    |    |    |    |    |    |    | RW      |    |    |    |    |    |    |    | RW      |    |    |    |    |    |   |   | RW      |   |   |   |   |   |   |   |

| Bit   | Name    | Function                   | Description                        | Access |
|-------|---------|----------------------------|------------------------------------|--------|
| 31:24 | ADDMAT3 | CS3 space matching address | CS3 space matching address setting | RW     |
| 23:16 | ADDMAT2 | CS2 space matching address | CS2 space matching address setting | RW     |
| 15:8  | ADDMAT1 | CS1 space matching address | CS1 space matching address setting | RW     |
| 7:0   | ADDMAT0 | CS0 space matching address | CS0 space matching address setting | RW     |

For example, when ADDMAT0 and ADDMSK0 are set to different values, the corresponding way of SMC access space is shown in the following table.

Table 40-34 CS0 Setting and Access Address Correspondence Table

| ADDMAT0[7:0] | ADDMSK0[7:0]            | Corresponding External Address | CS0 Space Size |
|--------------|-------------------------|--------------------------------|----------------|
| 0x70         | 0xFF                    | 0x70000000-0x70FFFFFF          | 16MB           |

Take ADDMAT0 and ADDMSK0 as examples to explain the corresponding method of DMC address space. The settings of other CS spaces are similar to CS0 settings.

Table 40-55 CS0 Setting and Access Address Correspondence Table

| Access |              |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   | RW      |   |          | RW      |   |   |   |   |

| Bit  | Name     | Function                        | Description                                              | Access |
|------|----------|---------------------------------|----------------------------------------------------------|--------|
| 31:7 | Reserved | Reserved                        | -                                                        | -      |
| 6:4  | T_RCD_P  | Additional T_RCD period setting | Additional T_RCD setting                                 | RW     |
| 3    | Reserved | Reserved                        | -                                                        | -      |
| 2:0  | T_RCD_B  | Basic T_RCD period setting      | Basic T_RCD setting, needs to be set to a non-zero value | RW     |

T\_RCD (RAS to CAS minimum delay time) is calculated as follows:

- When CKSTOP=0:
  - ▶ When T\_RCD\_B ≥ T\_RCD\_P+3, the actual T\_RCD width is T\_RCD\_B DMC module clock periods;
  - ▶ When T\_RCD\_B < T\_RCD\_P+3, the actual T\_RCD width is (T\_RCD\_P+3) DMC module clock periods.
- When CKSTOP=1:
  - ▶ When T\_RCD\_B ≥ T\_RCD\_P+2, the actual T\_RCD width is T\_RCD\_B DMC module clock periods;
  - ▶ When T\_RCD\_B < T\_RCD\_P+2, the actual T\_RCD width is (T\_RCD\_P+3) DMC module clock periods.

## 40.4.4.14 Timing Configuration Register (DMC\_TMCR\_T\_RFC)

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |         |    |    |    |          |    |   |   |         |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---------|----|----|----|----------|----|---|---|---------|---|---|---|---|---|---|---|
| 0x002C | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15      | 14 | 13 | 12 | 11       | 10 | 9 | 8 | 7       | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x00001012   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |         |    |    |    |          |    |   |   |         |   |   |   |   |   |   |   |
| Name   | Reserved     |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    | T_RFC_P |    |    |    | Reserved |    |   |   | T_RFC_B |   |   |   |   |   |   |   |
| Access |              |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    | RW      |    |    |    |          |    |   |   | RW      |   |   |   |   |   |   |   |

| Bit   | Name     | Function                         | Description               | Access |
|-------|----------|----------------------------------|---------------------------|--------|
| 31:13 | Reserved | Reserved                         | -                         | -      |
| 12:8  | T_RFC_P  | Additional T_RFC period settings | Additional T_RFC settings | RW     |
| 7:5   | Reserved | Reserved                         | -                         | -      |
| 4:0   | T_RFC_B  | Basic T_RFC period settings      | Basic T_RFC settings      | RW     |

T\_RFC (autorefresh command time) is calculated as follows:

- When  $T\_RFC\_B \geq T\_RFC\_P + 3$ , the actual T\_RFC width is T\_RFC\_B DMC module clock periods;
- When  $T\_RFC\_B < T\_RFC\_P + 3$ , the actual T\_RFC width is (T\_RFC\_P + 3) dMC module clock periods.

## 40.4.4.15 Timing Configuration Register (DMC\_TMCR\_T\_RP)

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |        |   |          |        |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|--------|---|----------|--------|---|---|---|---|
| 0x0030 | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7      | 6 | 5        | 4      | 3 | 2 | 1 | 0 |
| Reset  | 0x00000035   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |        |   |          |        |   |   |   |   |
| Name   | Reserved     |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   | T_RP_P |   | Reserved | T_RP_B |   |   |   |   |
| Access |              |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   | RW     |   |          | RW     |   |   |   |   |

| Bit  | Name     | Function                        | Description                                             | Access |
|------|----------|---------------------------------|---------------------------------------------------------|--------|
| 31:7 | Reserved | Reserved                        | -                                                       | -      |
| 6:4  | T_RP_P   | Additional T_RP period settings | Additional T_RP settings                                | RW     |
| 3    | Reserved | Reserved                        | -                                                       | -      |
| 2:0  | T_RP_B   | Basic T_RP period setting       | Basic T_RP setting, needs to be set to a non-zero value | RW     |

The calculation method of T\_RP is as follows:

- When CKSTOP=0:
  - ▶ When  $T\_RP\_B \geq T\_RP\_P + 3$ , the actual T\_RP width is T\_RP\_B DMC module clock periods;
  - ▶ When  $T\_RP\_B < T\_RP\_P + 3$ , the actual T\_RP width is (T\_RP\_P+3) DMC module clock periods.
- When CKSTOP=1:
  - ▶ When  $T\_RP\_B \geq T\_RP\_P + 2$ , the actual T\_RP width is T\_RP\_B DMC module clock periods;
  - ▶ When  $T\_RP\_B < T\_RP\_P + 2$ , the actual T\_RP width is (T\_RP\_P+3) DMC module clock periods.

| Bit  | Name     | Function | Description                                                                                 | Access |
|------|----------|----------|---------------------------------------------------------------------------------------------|--------|
| 31:8 | Reserved | Reserved | -                                                                                           | -      |
| 7:0  | IDX1     | Index    | The high 8 bits of the access address and the low 32 bits are composed of the IDX0 register | RW     |

IDXR0 and IDX1 together form the 40-bit address when accessing the NAND Flash device. The relationship between the value written to the register and the address of the actual device depends on the capacity of the device. The following table lists the address structure when accessing various capacity devices:

Table 40-99 Index Register Value and MEM Address Correspondence Table

| Capacity | 2K Page |        |       | 4K Page |        |       | 8K Page |        |       |
|----------|---------|--------|-------|---------|--------|-------|---------|--------|-------|

##### 4bitECC Mode

In 4bitECC mode, ECCR7-71 (Offset: 0x807C-0x817C) is used as the ECC status register and the syndrome register. As shown in the following table, 512 bytes are used as a segment, and each segment corresponds to 8 ECC syndrome coefficients. For example: The segment 0 syndrome register corresponds to the first 512 bytes of ECC value, and contains a total of 4 registers (segment 0 syndrome coefficient 1 and 2 registers (ECC\_SECTION0\_SYND12), segment 0 syndrome coefficient 3 and 4 registers (ECC\_SECTION0\_SYND34), segment 0 syndrome coefficient 5 and 6 registers (ECC\_SECTION0\_SYND56), segment 0 syndrome coefficient 7 and 8 registers (ECC\_SECTION0\_SYND78) ), each register contains 2 ECC syndrome coefficients.

Table 40-116 ECCR Register List in 4bitECC Mode

| Offset        | Register          | Description                  | Width | Reset value |
|---------------|-------------------|------------------------------|-------|-------------|
| 0x807C        | ECC_STAT          | ECC Status Register          | 32    | 0x00000000  |
| 0x8080-0x808C | ECC_SECTION0_SYND | Segment 0 Companion Register | 32    | 0x00000000  |

| Offset        | Register           | Description                   | Width | Reset value |
|---------------|--------------------|-------------------------------|-------|-------------|
| 0x8090-0x809C | ECC_SECTION1_SYND  | Segment 1 Companion Register  | 32    | 0x00000000  |

## 40.5 Precautions

1. The SMC related registers can only be set in the Ready state; the DMC related registers can only be set in the Config or Low Power state.
2. When using the SMC or DMC module to read external memory, the Memory Device transmits data to the controller after receiving the read command from the controller. The clock used by the controller to sample the data sent back can be selected through SMC\_BACR.CKSEL or DMC\_BACR.CKSEL. For specific settings, please refer to the register section. By selecting a different sampling clock, the time margin of the communication path can be improved.

SMC access in synchronous mode.

Figure 40-38 External Feedback Clock Access

3. When using the SMC and DMC functions, if you access the NFC register, you need to insert the NFC DUMMY read access after the access to clear the NFC access status.

## 41 Digital Video Port (DVP)

### 41.1 Introduction

Digital Video Port (DVP) is a synchronous parallel interface, which can collect 8-bit, 10-bit, 12-bit or 14-bit high-speed data streams from external CMOS camera modules. Support software synchronization and hardware synchronization. Support data stream acquisition frequency control and window clipping control. Supports data stream acquisition in various formats such as monochrome or raw Bayer format, YCbCr4:2:2, RGB565 progressive video, and compressed data (JPEG).

### 41.2 Features

The following table outlines the basic functions and features of DVP.

**Table 41-1 DVP Basic Functions and Features**

|                 |                                                    |
|-----------------|----------------------------------------------------|
| Basic function  | 8-bit, 10-bit, 12-bit, 14-bit Parallel Interface   |
|                 | Single Frame Mode and Continuous Mode              |
|                 | Software and Hardware Line/Frame Sync              |
|                 | Frame Acquisition Frequency Control                |
|                 | Window Cropping                                    |
|                 | FIFO Control                                       |
| Data format     | Monochrome or Raw Bayer Format                     |
|                 | YCbCr4:2:2 Progressive Video                       |
|                 | RGB565 Progressive Video                           |
|                 | JPEG Compressed Data                               |
| Interrupt event | Frame Start Interrupt and Event                    |
|                 | Frame End Interrupt and Event                      |
|                 | Line Start Interrupt and Event                     |
|                 | Line End Interrupt and Event                       |
|                 | Software Synchronization Error Interrupt and Event |
|                 | FIFO Overflow Error Interrupt and Event            |

## 41.3 Functional Description

### 41.3.1 System Block Diagram

Figure 41-1 DVP Basic Block Diagram

The following table lists the input ports of DVP.

Table 41-2 DVP Port List

| Port Name      | Direction | Function                         |
|----------------|-----------|----------------------------------|
| DVP_VSYNC      | Input     | Frame synchronization input port |
| DVP_HSYNC      | Input     | Line synchronization input port  |
| DVP_PIXCLK     | Input     | Clock input port                 |
| DVP_DATA[13:0] | Input     | Data input port                  |

### 41.3.2 Video Data Format

#### Monochrome Format

- Each pixel is 8 bits.

The following table shows how the data is stored.

Table 41-3 Monochrome Format Video Data Storage Method

| Byte Address | 31:24 | 23:16 | 15:8 | 7:0 |
|--------------|-------|-------|------|-----|
| 0x00         | n+3   | n+2   | n+1  | n   |
| 0x04         | n+7   | n+6   | n+5  | n+4 |

#### YCbCr Format

- Alternating storage of Y, Cb, and Cr in one buffer: CbYCrYCbYCr...
- DVP module support for YCbCr4:2:2 format data transfer with pixel components including Y (luminance), Cb and Cr (Blue chrominance and red chrominance). Each component is encoded in 8 bits, with luminance and chrominance stored alternately.

The following table shows how the data is stored.

Table 41-4 YCbCr Format Video Data Storage Method

| Byte Address | 31:24 | 23:16  | 15:8  | 7:0    |
|--------------|-------|--------|-------|--------|
| 0x00         | Y n+1 | Cr n   | Y n   | Cb n   |
| 0x04         | Y n+3 | Cr n+2 | Y n+2 | Cb n+2 |

#### RGB565 Format

- Alternating storage of RGB signals in one buffer: BGRBGRBGR...
- DVP module support for 16BPP (16 bits per pixel) : RGB565 (2 pixels represented in 32 bits), does not support 24BPP (palette format) and grayscale formats.

The following table shows how the data is stored.

Table 41-5 RGB565 Format Video Data Storage Method

| Byte Address | 31:27 | 26:21 | 20:16 | 15:11 | 10:5  | 4:0   |
|--------------|-------|-------|-------|-------|-------|-------|
| 0x00         | R n+1 | G n+1 | B n+1 | R n   | G n   | B n   |
| 0x04         | R n+3 | G n+3 | B n+3 | R n+3 | G n+3 | B n+3 |

#### JPEG Format

- JPEG image not stored by lines and frames. DVP\_VSYNC signal initiates acquisition, DVP\_HSYNC serves as data enable signal.
- The number of bytes in the active interval of DVP\_HSYNC may not be a multiple of 4.
- DVP module supports JPEG format data transfer (DVP\_CTR.JPEGEN=1).

### 41.3.3 Parallel Port Storage Format

DVP interface consists of 11, 13, 15, or 17 input signals. Supports slave mode only. Collects 8-bit, 10-bit, 12-bit, or 14-bit data based on DVP\_CTR.BITSEL setting.

Data DVP\_DATA output by the camera module synchronizes with pixel clock DVP\_PIXCLK, changing on the rising/falling edge of DVP\_PIXCLK based on its polarity; DVP\_VSYNC indicates frame start/end; DVP\_HSYNC indicates line start/end.

During DVP\_VSYNC or DVP\_HSYNC activity, it represents the synchronization interval, and data transfer is disabled; when both are inactive, it represents the data interval, and data transfer is enable. The signal waveform diagram shows that DVP\_DATA changes on the rising edge of DVP\_PIXCLK (the DVP module is configured to sample data DVP\_DATA on the falling edge of DVP\_PIXCLK). DVP\_VSYNC or DVP\_HSYNC are in synchronization intervals when at high level, and data transmission is disabled during these intervals.

Figure 41-2 DVP Signal Waveform Diagram

## 8-bit Data

When DVP\_CTR.BITSEL=0b00, the DVP interface collects 8-bit data from DVP\_DATA[7:0] and stores it as 8-bit data, ignoring the input of DVP\_DATA[13:8]. In this case, a 32-bit data word is generated for every four pixel clock periods. The following table lists the bit arrangement of captured data bytes in two 32-bit words.

Table 41-6 8-bit Data DVP Storage Method

| Byte Address | 31:24     | 23:16     | 15:8      | 7:0       |
|--------------|-----------|-----------|-----------|-----------|
| 0x00         | Dn+3[7:0] | Dn+2[7:0] | Dn+1[7:0] | Dn[7:0]   |
| 0x04         | Dn+7[7:0] | Dn+6[7:0] | Dn+5[7:0] | Dn+4[7:0] |

## 10-bit Data

When DVP\_CTR.BITSEL=0b01, the DVP interface collects 10-bit data from DVP\_DATA[9:0] and stores it in the 10 least significant bits of a 16-bit word, ignoring the input of DVP\_DATA[13:10]. At that time, the remaining most significant bits (Bit15-10) in the DVP\_DTR register are cleared. In this case, one 32-bit data word is generated every two pixel clock periods, as shown in the table below.

Table 41-7 10-bit Data DVP Storage Method

| Byte Address | 31:24 | 23:16     | 15:8 | 7:0       |
|--------------|-------|-----------|------|-----------|
| 0x00         | 0     | Dn+1[9:0] | 0    | Dn[9:0]   |
| 0x04         | 0     | Dn+3[9:0] | 0    | Dn+2[9:0] |

## 12-bit Data

When DVP\_CTL.BITSEL=0b10, the DVP interface collects 12-bit data from DVP\_DATA[11:0] and stores it in the 12 least significant bits of a 16-bit word, ignoring the input of DVP\_DATA[13:12]. At that time, the remaining most significant bits (Bit15-12) in the DVP\_DTR register are cleared. In this case, one 32-bit data word is generated every two pixel clock periods, as shown in the table below.

Table 41-8 12-bit Data DVP Storage Method

| Byte Address | 31:24 | 23:16      | 15:8 | 7:0        |
|--------------|-------|------------|------|------------|
| 0x00         | 0     | Dn+1[11:0] | 0    | Dn[11:0]   |
| 0x04         | 0     | Dn+3[11:0] | 0    | Dn+2[11:0] |

## 14-bit Data

When DVP\_CTL.BITSEL=0b11, the DVP interface collects 14-bit data from DVP\_DATA[13:0] and stores it in the 14 least significant bits of a 16-bit word. At that time, the remaining most significant bits (Bit15-14) in the DVP\_DTR register are cleared. In this case, one 32-bit data word is generated every two pixel clock periods, as shown in the table below.

Table 41-9 14-bit Data DVP Storage Method

| Byte Address | 31:24 | 23:16      | 15:8 | 7:0        |
|--------------|-------|------------|------|------------|
| 0x00         | 0     | Dn+1[13:0] | 0    | Dn[13:0]   |
| 0x04         | 0     | Dn+3[13:0] | 0    | Dn+2[13:0] |

## 41.3.4 Mode Selection

### 41.3.4.1 Single Frame Mode

In single frame mode (DVP\_CTL.CAPMD=1), only one frame is captured. After setting DVP\_CTL.CAPEN bit to 1, the DVP interface waits for the system to detect frame start and then collects data. Upon receiving a complete frame of data, the CAPEN bit in DVP\_CTL is automatically cleared, and the camera interface stops receiving data. If frame end interrupt is enabled, a corresponding interrupt or event (DVP\_FRAMEND) is generated.

Figure 41-3 Single Frame Mode Data Acquisition Action

### 41.3.4.2 Continuous Mode

In continuous mode (`DVP_CTR.CAPMD=0`), image frames are continuously captured. After setting `DVP_CTR.CAPEN` bit to 1, the DVP interface waits for the system to detect frame start and then collects data. This process continues until the `CAPEN` bit in `DVP_CTR` is cleared. After the CPU issues a software clear action on the `DVP_CTR.CAPEN` bit, data acquisition continues until the current frame ends, then the `DVP_CTR.CAPEN` bit is cleared.

Figure 41-4 Continuous Mode Data Acquisition Action

In continuous mode, the frame capture frequency can be controlled by setting the `DVP_CTR.CAPFRC[1:0]` bits to reduce bandwidth. For example, when `DVP_CTR.CAPFRC[1:0]=0b01`, the camera interface samples the input data at intervals, that is, it collects image data once every frame.

Figure 41-5 Frame Acquisition Frequency Control

## 41.3.5 Synchronization Control

### 41.3.5.1 Software Synchronization

In software synchronization mode, a 32-bit synchronization code embedded in the data stream is used to synchronize the data stream. These synchronization codes use unused `0x00/0xFF` in the data stream. There are four types of synchronization codes, all in the format `0xFF0000XY`. The DVP interface determines frame synchronization status by collecting a 32-bit word of data.

Four software synchronization codes represent the following events:

- Frame Start FS (`DVP_SSYNDR.FSDAT[7:0]`)
- Line Start LS (`DVP_SSYNDR.LSDAT[7:0]`)
- Line End LE (`DVP_SSYNDR.LEDAT[7:0]`)

- Frame End FE (DVP\_SSYNDR.FEDAT[7:0])

The XY in the synchronization code format 0xFF0000XY is determined by the four sets of register bits mentioned above. For example, when the captured data XY matches DVP\_SSYNDR.FSDAT[7:0], it indicates the start of a frame data transfer.

The four synchronization codes also have a bit masking function, allowing only the unmasked bits of the synchronization code to be used for comparison. The masking bits for each synchronization code are set by the corresponding bits in DVP\_SSYNMR. When the masking function is enabled, a single bit can be selected for synchronization code comparison to detect frame/line start and end. This means multiple synchronization codes can represent frame/line start and end as long as the unmasked bits match. For example, when DVP\_SSYNDR.FSDAT[7:0] is set to 0xA5 and DVP\_SSYNMR.FSMASK[7:0] is set to 0xF0, only the upper 4 bits of the data code need to be compared to detect the FS signal.

According to the software synchronization mechanism, DVP only supports 8-bit data format interfaces (DVP\_CTR.BITSEL[1:0]=0b00) and full-frame capture (DVP\_CTR.CAPFRC[1:0]=0b00). Other data width formats or frame skipping modes are not applicable and may produce unpredictable results. JPEG format data transfer is also not supported (DVP\_CTR.JPEGEN=0).

#### 41.3.5.2 Hardware Synchronization

In hardware synchronization mode, two port synchronization signals (DVP\_VSYNC/DVP\_HSYNC) are used. The camera interface module determines the start and end of frames/lines based on the level changes of DVP\_VSYNC/DVP\_HSYNC.

When data stream capture function is enabled in hardware synchronization mode (DVP\_CTR.CAPEN=1), data transfer can start after an inactive edge is detected on the DVP\_VSYNC port. Continuous frames are transferred to multiple consecutive buffers or a buffer with circular features by DMA. A frame transfer end interrupt is activated at the end of each frame (when the frame transfer end interrupt DVP\_FRAMEND is enabled).

#### 41.3.6 Window Cropping

The camera interface can use the cropping function to select a rectangular window from the received image. The starting coordinates and size of the window (horizontal size in pixel clock counts, vertical size in row counts) are specified by the window cropping offset register (DVP\_CPSFTR) and window cropping size register (DVP\_CPSZER).

Figure 41-6 DVP Window Configuration Diagram

The starting coordinates of the cropping window are specified as a row number (starting from 0) and a pixel clock count (starting from 0), and the window size is specified as the number of rows and pixel clock counts. If the DVP\_VSYNC signal becomes active before the number of rows specified in the window cropping size register (DVP\_CPSZER) is completed, image capture stops, and a frame transfer end interrupt (DVP\_FRAMEND) is generated if interrupts are enabled. The following figure is a schematic diagram of window cropping data acquisition.

Figure 41-7 Window Cropping Data Acquisition Diagram

When JPEG format data transfer is enabled (`DVP_CTR.JPEGEN=1`), the window cropping function is not applicable, and the window cropping function must be disabled.

### 41.3.7 FIFO Control

To manage the data transfer speed on AHB, an 8-word deep FIFO is equipped in the DVP module with a FIFO controller. The read pointer increments each time data is read from the camera interface FIFO, and the write pointer increments each time data is written to the camera interface FIFO. If the data write speed exceeds the rate that the AHB interface can handle, the FIFO will overflow, and data will be overwritten. At this time, if the FIFO overflow error interrupt is enabled, a corresponding interrupt will be generated.

If a software synchronization error event occurs, the FIFO will be reset, and the DVP interface will wait for the start of a new data frame.

### 41.3.8 DMA Control

When `DVP_CTR.CAPEN=1`, the DMA interface is activated. Each time the camera interface receives a complete 32-bit data block in the data register (`DVP_DTR`), it can trigger a DMA read request. When DMA accesses the DMA data transfer register (`DVP_DMR`) through the AHB interface, it reads the corresponding cached data from the FIFO. This DMA read request is event number 90 in the event list. For more information, refer to the "Interrupt Event List" in the Interrupt Controller (INTC) chapter. For DMA settings, refer to the "DMA Controller" chapter.

When transmitting JPEG data, the number of bytes in a line may not be a multiple of 4. The DVP interface will pad with zeros when it detects the end of a line and has not yet formed a 32-bit word, and trigger a DMA read request.

### 41.3.9 Interrupt and Events

#### 41.3.9.1 Frame Transfer Status Interrupt and Event

During normal image frame transfer, interrupts can be generated for various states:

Table 41-10 Frame Transfer Interrupt

| Interrupt/Event Name | Interrupt/Event Symbol   | Interrupt Enable Bit    |
|----------------------|--------------------------|-------------------------|
| Frame transfer start | <code>DVP_FRAMSTA</code> | <code>IER.FSIEN</code>  |
| Line transfer start  | <code>DVP_LINESTA</code> | <code>IER.LSIEN</code>  |
| Line transfer end    | <code>DVP_LINEEND</code> | <code>IER.LEIEN</code>  |
| Frame transfer end   | <code>DVP_FRAMEND</code> | <code>IER.FEIEEN</code> |

#### 41.3.9.2 Software Synchronization Error Interrupt and Event

In software synchronization mode, if the received synchronization code exhibits an error sequence as shown in the following table, the corresponding status bit (`DVP_STR.SQUERF`) will be set to 1. If the corresponding interrupt enable (`DVP_IER.SQUERIEN`) is set to be valid, a software synchronization error (`DVP_SQUERR`) interrupt will be generated.

Table 41-11 Synchronization Code Error Sequence

| FS | LS | LE | FE |
|----|----|----|----|
| 0  | 0  | 0  | 1  |
| 0  | 0  | 1  | x  |
| 0  | 1  | x  | x  |

| FS | LS | LE | FE |
|----|----|----|----|
| 1  | 0  | 1  | x  |
| 1  | 1  | 0  | 1  |

In the table, 1 indicates the synchronization sequence is received, 0 indicates it is not received, and x indicates whether the sequence is received does not affect the sequence error judgment.

For example, when FS:LS:LE:FE=0b1101, it indicates that after receiving the frame start and line start sequences, the frame end sequence is received, but the line end sequence is not received, resulting in a software synchronization sequence error event.

When a synchronization code error occurs, the internal frame capture control logic will reset, and no data from the current frame will be received until DVP\_STR.SQUERF is cleared, at which point the start of the next frame's frame start sequence will be received and monitored.

#### 41.3.9.3 FIFO Overflow Error Interrupt and Event

When a FIFO overflow occurs, the corresponding status bit (DVP\_STR.FIFOERF) will be set to 1. If the corresponding interrupt enable (DVP\_IER.FIFOERIEN) is set to be valid, a FIFO overflow error (DVP\_FIFOERR) interrupt will be generated.

## 41.4 Register Description

### 41.4.1 Register List

Base address: 0x40055800

Table 41-12 Digital Video Port (DVP) Register Offset

| Offset | Register   | Description                            | Width |
|--------|------------|----------------------------------------|-------|
| 0x0000 | DVP_CTR    | Control Register                       | 32    |

## 42 Cryptographic Coprocessing Module (CPM)

### 42.1 Introduction

The Cryptographic Coprocessing Module (CPM) includes four sub-modules: HASH Secure Hash Algorithm, TRNG True Random Number Generator, PKE Public Key Engine, and SKE Symmetric Encryption Algorithm Module.

- HASH is the SHA-2 version of SHA-256 (Secure Hash Algorithm), which complies with the national standard "FIPS PUB 180-3" issued by the US National Institute of Standards and Technology, and can generate a 256-bit message digest output for messages with a length of up to  $2^{64}$  bits. Supports HMAC (Hash-based Message Authentication Code) applications, using the SHA-256 hash function to authenticate messages.
- TRNG is a random number generator based on continuous analog noise, providing 64-bit random numbers.
- PKE implements hardware acceleration for asymmetric signature/verification or encryption/decryption algorithms.
- SKE includes three algorithms: AES, DES, and SM4, and eight operating modes: ECB, CBC, CTR, CFB, OFB, GCM, CCM, and CMAC.

### 42.2 Features

#### 42.2.1 PKE Features

- Supports modular arithmetic: modular addition, modular subtraction, modular multiplication, modular exponentiation, and modular inverse
- Supports elliptic curve point operations: point addition, point doubling, point multiplication, and point-on-curve verification
- Supports big number operations: large integer multiplication
- Supports both interrupt and polling modes for status monitoring

#### 42.2.2 SKE Features

SKE supports 5 algorithms: AES-128, AES-192, AES-256, DES and SM4, among which: AES and SM4 support 8 working modes, including ECB, CBC, CTR, CFB, OFB, GCM, CCM and CMAC; DES supports 6 working modes except GCM and CCM.

## 42.3 Functional Description

### 42.3.1 Secure Hash Algorithm (HASH)

#### 42.3.1.1 Algorithm Introduction

The steps of the secure hash algorithm are as follows:

First pad the message so that its length is exactly a number that is only 64 bits less than a multiple of 512. The padding method is to attach a 1 to the back of the message, followed by the required multiple 0s, and then attach a 64-bit message length (before padding) to make the message length exactly an integer multiple of 512 bits.

Secondly, initialize the eight 32-bit variables A, B, C, D, E, F, G, and H in hexadecimal. Then start the main loop of the algorithm, process 512-bit messages at a time, the number of loops is the number of 512-bit packets in the message.

The main loop performs a total of 64 operations, which are called compression functions. Each operation includes shift, circular shift, logical operation, modulo 232 addition, etc. The operation process is shown in the figure below. The final output is the cascade of A, B, C, D, E, F, G, and H. Among them,  $W_t$  is the temporary value used in the  $t$ -th step obtained from the 512-bit message,  $K_t$  is the constant value used in the  $t$ -th step, and  $t$  ( $0 \leq t \leq 63$ ) is a step in the 64-step period.

Figure 42-1 HASH Algorithm Flowchart

The HASH module integrates the hardware HMAC function; the HMAC function can also be implemented by directly calling the HASH operation according to the HMAC algorithm through software.

#### 42.3.1.2 Operating Procedures

The operation process of the HASH module is as follows:

- Software operation process

- Step1.** The software fills the original data according to the algorithm rules, and groups the filled messages by 512 bits.
- Step2.** Write the data into the HASH\_DR register.
- Step3.** If this operation is the first group of data in the message group, set HASH\_CR.FST\_GRP=1.
- Step4.** Set HASH\_CR.START=1 to start this module for operation.

##### Note

Steps 3 and 4 can be performed at the same time.

- Step5.** To judge whether the operation of this module is completed, use the following methods: Keep reading HASH\_CR.START until the bit is 0, which means the operation is complete; Or keep reading HASH\_CR.BUSY until the bit is 0, which means the operation is completed; Or set the HASH interrupt to determine the end of the operation through the interrupt method.
- Step6.** If this operation is not the last set of data in the message grouping, return to step 2.
- Step7.** If this operation is the last set of data in the message group, read the summary register (HASH\_HR) to obtain the result of this operation. If you need to perform the calculation again, return to step 1.

- Using DMA operation process:

- Step1.** The messages to be processed are grouped into 512-bit blocks, and the last group of messages needs to be pre-filled into 512-bit blocks according to the rules.
- Step2.** Set the HASH operation start mode of the internal trigger event register to DMA transfer completion and data block transfer completion; set the DMA transfer start mode of the internal trigger event register to HASH operation completion (or other internal trigger events).
- Step3.** Set HASH\_CR.MODE=0b00, HASH operation mode; set HASH\_CR.FST\_GRP=1, and set HASH\_CR.START=1 to start HASH operation. If another internal trigger event is selected to initiate DMA, it is necessary to wait for the trigger event to occur before starting the HASH computation.
- Step4.** Wait for HASH\_CR.CYC\_END=1, the HASH operation is completed, and the bit is cleared.
- Step5.** Read the result from the hash digest register HASH\_HR.

##### Note

When there is only one set of operation data, set both HASH\_CR.FST\_GRP=1 and HASH\_CR.KMSG\_END=1 simultaneously.

#### 42.3.1.3 Message Padding

The padding packet processing steps of SHA-256 are as follows:

- Step1.** Raw message grouping

Divide the original message into L groups of 512 bits in size. Let the total number of bits of the original message be I. If  $I \% 512 < 448$ , then the grouping number L is  $I / 512$ ; if  $I \% 512 \geq 448$ , then the grouping number L is  $I / 512 + 1$ .

**Step2. Add length****a. Add padding:**

Add padding bits at the end of the  $l/512$ th group of the message packet: one 1 and several 0s, the number of 0s can be zero. If  $l\%512 < 448$ , pad the data bits to make the length satisfy  $448 \bmod 512$  (the last 64 bits are reserved to represent the length of the original message); if  $l\%512 \geq 448$ , fill the 512-bit data block of the  $l/512$ th group with a 1 and several 0s, and fill the first 448 bits of the  $L$ th ( $L=l/512+1$ ) th group with 0s.

**b. Add raw message length:**

A 64-bit block representing the original message length, as a 64-bit unsigned integer. Add the original message length to the last 64-bit of the  $L$ th packet.

An example to illustrate the process of filling a group is as follows:

**● Example 1**

The original message is a string of characters "abcde". Its ASCII code is represented by a binary bit string as follows: "01100001 01100010 01100011 01100100 01100101". The steps to add the length are as follows:

1. Add "1". The filled message is "01100001 01100010 01100011 01100100 01100101 1".
2. Add "0". Since the original message length is 40-bit, the number of zeros to be added is  $512-64-40-1=407$ .

The padded message becomes (hex) :

```
61626364 65800000 00000000 00000000
00000000 00000000 00000000 00000000
00000000 00000000 00000000 00000000
00000000 00000000
```

3. Add the original message length. The original message length is 40-bit, expressed as two 32-bit words (hexadecimal) : 00000000 00000028.

The padded message becomes (hex) :

```
61626364 65800000 00000000 00000000
00000000 00000000 00000000 00000000
00000000 00000000 00000000 00000000
00000000 00000000 00000000 00000028
```

**● Example 2**

The original message is the string "abcbcdcedefdefgefghfghighijhijkijkljklmklmnlmnomnopnopq". Each character can be converted to 8-bit by its ASCII code, so the length of the message is  $l=56 * 8=448$ .

1. Add "1" and "0". The padded message (hexadecimal) is the first message block:

```
61626364 62636465 63646566 64656667
65666768 66676869 6768696A 68696A6B
696A6B6C 6A6B6C6D 6B6C6D6E 6C6D6E6F
6D6E6F70 6E6F7071 80000000 00000000
```

2. Add the original message length. The original message length is 448-bit, expressed as two 32-bit words (in hexadecimal) : 00000000 000001C0.

The padded message (hexadecimal) is the second message block:

```
00000000 00000000 00000000 00000000
00000000 00000000 00000000 00000000
00000000 00000000 00000000 00000000
00000000 00000000 00000000 000001C0
```

#### 42.3.1.4 HMAC Operation

HMAC (Keyed-Hashing for Message Authentication) binds the message being processed to a key selected by the user in an irreversible manner for message authentication. Basically, HMAC consists of two nested underlying HASH operations with the addition of a shared secret:

$$\text{HMAC}(\text{message}) = \text{Hash}[(\text{key XOR opad}) \mid \text{Hash}((\text{key XOR ipad}) \mid \text{message})]$$

Where:

- iPad: 64 bytes (SHA-256) 0x36.
- opad: 64 bytes (SHA-256) 0x5C.
- |: represents the concatenation operator.

##### 42.3.1.4.1 HMAC Operation Process

- Step1.** Set HASH\_CR.MODE=0b01 to select HMAC operation mode;
- Step2.** If the key length exceeds 64 bytes, set HASH\_CR.LKEY=1 (in this case, HMAC will use a key as specified by the standard, replacing the given key).
- Step3.** Write the key into the HASH\_DR register until all key group operations are completed.
- Step4.** Write the message into the HASH\_DR register until all message group operations are completed.
- Step5.** Read the final hash result from the HASH\_HR register.

For data loading during the HMAC operation, either a software operation flow or DMA operation flow can be chosen. Specific examples are provided below:

##### ● HMAC Software Operation Flow

- Step1.** Set HASH\_CR.MODE=0b01 to select HMAC operation mode; Set HASH\_CR.LKEY=1 to select the long key mode.
- Step2.** Write the key group data into HASH\_DR register;
- Step3.** If it is the first data group, set HASH\_CR.FST\_GRP=1. Set HASH\_CR.START=1 to start key operation.
- Step4.** Wait until HASH\_CR.BUSY=0 indicating operation completion.
- Step5.** If it is not the last data group, repeat steps 2-4;
- Step6.** If it is the last data group, set HASH\_CR.KMSG\_END=1, and then set HASH\_CR.START=1 to start the last key operation. Wait until HASH\_CR.CYC\_END=1, indicating key operation completion, then clear this bit.
- Step7.** Write the message group data into the HASH\_DR register.
- Step8.** If it is the first message group, set HASH\_CR.FST\_GRP=1. Set HASH\_CR.START=1 to start the message operation.
- Step9.** Wait until HASH\_CR.BUSY=0 indicating operation completion.
- Step10.** If it is not the last message group, repeat steps 7-9.
- Step11.** If it is the last message group, set HASH\_CR.KMSG\_END=1, and then set HASH\_CR.START=1 to start the final message operation. Wait until HASH\_CR.CYC\_END=1, indicating all HMAC operations are completed, then clear this bit.
- Step12.** Read the final message authentication result from the HASH\_HR register.

### ● HMAC Uses DMA Operation Process

- Step1.** Set DMA to data block transmission mode. The size of the data block is 16 words. Both the key and the message need to be grouped according to the size of 16 words. If it is less than 16 words, please fill it according to the HASH message filling rules. Configure the DMA data block source address as the key address;
- Step2.** Set the HASH operation start mode of the internal trigger event register to DMA transfer completion and data block transfer completion; set the DMA transfer start mode of the internal trigger event register to HASH operation completion (or other internal trigger events);
- Step3.** Set HASH\_CR.MODE=0b01, HMAC operation mode; configure HASH\_CR.LKEY bit according to the key length; set HASH\_CR.FST\_GRP=1, HASH\_CR.START=1 to start the key operation; if other internal trigger events are selected, you need to wait for the trigger event to start the operation;
- Step4.** After waiting for HASH\_CR.CYC\_END=1, the key operation is completed and then clear this bit;
- Step5.** Stop DMA and point the DMA data block source address to the message address;
- Step6.** Set HASH\_CR.FST\_GRP=1, HASH\_CR.START=1 to start the message operation; or wait for other trigger events to start the message operation.
- Step7.** After waiting for the HASH\_CR.CYC\_END=1 message operation to complete, clear this bit;
- Step8.** Read the final message authentication result in the HASH\_HR register.

#### 42.3.1.5.2 Hardware Trigger Event Selection

The internal hardware trigger event selection registers HASH\_TRGSELA and HASH\_TRGSELB are configured to start the HASH operation after data transmission completion, typically used in conjunction with DMA. For example, when DMA\_2 is selected to transfer data and start HASH operation, first, configure DMA2\_TRGSELx (x=0-7) to select HASH\_INT to start DMA transfer; secondly, configure HASH\_TRGSELA to select DMA\_BTCx (x=0-7), indicating that a data block (512-bit) transfer is completed and the HASH operation is started, and configure HASH\_TRGSELB to select DMA\_TCx (x=0-7), indicating that all data block transfers are completed. After starting the HASH operation, DMA and HASH trigger each other until all data blocks have been transferred and processed.

### 42.3.2 True Random Number Generator (TRNG)

#### 42.3.2.1 Module Block Diagram

The TRNG module provides a true random number generator to generate a 64-bit random number.

The system block diagram of the TRNG is shown below. The random number generator is an analog random number oscillator circuit, which is used to obtain random noise; the algorithm module captures random noise and saves the result to the data module, and outputs it through the bus; the control module controls the mode and start of TRNG.

Figure 42-2 TRNG System Block Diagram

#### 42.3.2.2 Operating Procedures

The true random number generation process is as follows:

- Step1.** Turn on the random number generator circuit (set TRNG\_CR.EN bit to 1).
- Step2.** Configure the random number generation mode (set TRNG\_MR).
- Step3.** Start random number generation (set TRNG\_CR.RUN bit to 1).
- Step4.** Read random number (read TRNG\_DR).
- Step5.** Turn off the random number generator circuit (set TRNG\_CR.EN bit to 0).

### 42.3.2.3 Interrupt and Events

When the random number generation is finished, the TRNG\_CR.RUN bit is cleared by hardware and generates a random number generation interrupt request (TRNG\_END). When the random number generation ends, an event output is also generated, which can trigger the linkage of other modules.

## 42.3.3 Public Key Engine (PKE)

### 42.3.3.1 Module Introduction

The PKE (Public Key Engine) system of this product consists of one computation module and two dedicated RAM blocks. Compatible with software drivers, the system supports RSA (RSA1024/RSA2048/RSA3072/RSA4096), ECC (brainpoolp 160/brainpoolp 256/brainpoolp 512/SECP 192/SECP 224/SECP 256/SECP 384/SECP 521), and SM2.

Table 42-2 Operation Speed

| Operation mode         |                                 |                           | Speed (ops/sec) | Module Clock Frequency |
|------------------------|---------------------------------|---------------------------|-----------------|------------------------|
| Hardware Maximum Speed | 256-bit Point Multiplication    |                           | 75              | 120MHz                 |
|                        | 1024-bit Modular Exponentiation |                           | 32.4            |                        |
| Software Maximum Speed | ECC SECP256R1                   | ECDSA/ECDH Key Generation | 72              |                        |
|                        |                                 | ECDH Key Exchange         | 75              |                        |
|                        |                                 | ECDSA Signature           | 72              |                        |
|                        |                                 | ECDSA Verification        | 36              |                        |
|                        | SM2                             | SM2 Key Generation        | 72              |                        |
|                        |                                 | SM2 Key Exchange          | 45              |                        |
|                        |                                 | SM2 Signature             | 72              |                        |
|                        |                                 | SM2 Verification          | 36              |                        |
|                        |                                 | SM2 Encryption            | 36              |                        |
|                        |                                 | SM2 Decryption            | 69              |                        |
|                        | ECC SECP384R1                   | ECDSA/ECDH Key Generation | 30              |                        |
|                        |                                 | ECDH Key Exchange         | 30              |                        |
|                        |                                 | ECDSA Signature           | 30              |                        |
|                        |                                 | ECDSA Verification        | 14.4            |                        |

#### 42.3.3.2 Module Block Diagram

The PKE module offloads the CPU from complex public-key cryptographic computations. The CPU only needs to configure the input parameters, and the PKE will automatically perform the specified operation based on the current configuration. Currently, the PKE supports modular exponentiation for RSA and point multiplication for ECC. The CPU can monitor the PKE's operation status via polling or interrupt.

The PKE consists of a program storage unit (ROM), an Instruction Execution Unit (IEU), a 32-bit Arithmetic Logic Unit (ALU), a register file, and an interface module.

Figure 42-3 PKE System Block Diagram

#### 42.3.3.3 Programming Model

All external memory used by the PKE is mapped into the bus address space. This address mapping primarily includes all operands and computation results accessible by the CPU. The operands include the modulus, exponent, and certain intermediate variables.

In addition, the address space also contains PKE control and status registers. The CPU can configure and monitor the PKE module through these control and status registers.

In typical public-key cryptographic operations, the shortest operand is 192 bits. When writing data into the data RAM, word-endianness issues may arise. In the PKE module, words are arranged in little-endian order. The minimum operand width supported by the PKE is 32 bits (one word). If the operand width is not a multiple of 32 bits, zero-padding must be added to the higher bits before inputting the operand externally.

After triggering a PKE operation, the running status of the PKE can be checked through the status register. The completion of the target operation can be detected via polling or interrupt.

#### Note

The data RAM is word-aligned and does not support byte alignment.

Table 42-3 RAM Operand Mapping

| RAM  | Operand Space | ECC     |         |          | RSA     |          |          |          |
|------|---------------|---------|---------|----------|---------|----------|----------|----------|
|      |               | 256-bit | 512-bit | 1024-bit | 512-bit | 1024-bit | 2048-bit | 4096-bit |
| RAM0 | A0            | 0x1400  | 0x1400  | 0x1400   | 0x1400  | 0x1400   | 0x1400   | 0x1400   |

|      | B7            | 0x20FC  | 0x21DC  | 0x239C   | -       | -        | -        | -        |
|      | B8            | 0x2120  | 0x2220  | 0x2420   | -       | -        | -        | -        |
|      | B9            | 0x2144  | 0x2264  | 0x24A4   | -       | -        | -        | -        |

The table above shows the address allocation of the two RAM blocks under different operand lengths for ECC and RSA modes. Operand registers are distributed across two data RAMs, distinguished by the prefixes A and B. The addresses listed in the table are CPU-accessible addresses: RAMA has an address offset of 0x1400, while RAMB has an address offset of 0x2000. The actual memory space used in RAM is larger than what is shown in the table, as part of the space is reserved for storing intermediate variables that are not accessible by the CPU.

- In ECC mode, the PKE uses register spaces 0 to 9 in both RAMs. Each register space supports three configurations: (8+1) words, (16+1) words, and (32+1) words, with 1 extra word reserved for possible carry storage.
- In RSA mode, the PKE uses register spaces 0 to 4 in both RAMs. Each register space supports four configurations: (16+1) words, (32+1) words, (64+1) words, and (128+1) words, with 1 extra word reserved for possible carry storage.

#### 42.3.3.4 Programming Entry

All programs are based on the procedure entry address shown in the table below.

Table 42-4 Programming Entry Address

| Procedure Name | Procedure Entry Address | Description                            |
|----------------|-------------------------|----------------------------------------|
| PDBL           | 0x04                    | Elliptic Curve Point Doubling          |
| PADD           | 0x08                    | Elliptic Curve Point Addition          |
| PVER           | 0x0C                    | Verify If Point Lies on Elliptic Curve |
| PMUL           | 0x10                    | Elliptic Curve Point Multiplication    |

| Procedure Name | Procedure Entry Address | Description               |
|----------------|-------------------------|---------------------------|
| MODEXP         | 0x14                    | Modular Exponentiation    |
| MODMUL         | 0x18                    | Modular Multiplication    |
| MODINV         | 0x1C                    | Modular Inversion         |
| MODADD         | 0x20                    | Modular Addition          |
| MODSUB         | 0x24                    | Modular Subtraction       |
| CAL_PRE_MON    | 0x28                    | Montgomery Precomputation |
| IMUL           | 0x2C                    | Big Number Multiplication |

## 42.3.4 Symmetric Encryption Algorithm Module (SKE)

### 42.3.4.1 Algorithm Introduction

The symmetric encryption algorithm module (SKE) contains a symmetric encryption algorithm engine and supports the following functions:

- AES encryption and decryption algorithm
- DES encryption and decryption algorithm
- SM4 encryption and decryption algorithm
- Support 8 operating modes, which are ECB, CBC, CTR, CFB, OFB, GCM, CCM and CMAC, and support data interleaving in GCM, CCM and CMAC modes.
- Support encryption and decryption completion interrupt

The AES encryption and decryption algorithm complies with the description of the algorithm principle in "FIPS PUB 197". The block length is fixed at 128 bits, and the key length supports 128/192/256 bits.

The DES encryption and decryption algorithm complies with the description of the algorithm principle in "FIPS PUB 46-3". The block length is fixed at 64 bits and the key length is 64 bits.

The SM4 encryption and decryption algorithm complies with the description of the algorithm principle in "GMT0002-2012". The block length is fixed at 128 bits and the key length is 128 bits.

### 42.3.4.2 Module Block Diagram

Figure 42-4 SKE System Block Diagram

### 42.3.4.3 Working Mode Description

- ECB: Electronic Code Book mode defined by NIST SP800-38A
- CBC: Cipher Block Chaining mode defined by NIST SP800-38A
- CTR: Counter mode defined by NIST SP800-38A, specifically CTR-32, refer to RFC 3686 standard
- CFB: Cipher Feedback mode defined by NIST SP800-38A, specifically CFB-128
- OFB: Output Feedback mode defined by NIST SP800-38A
- GCM: Galois/Counter mode defined by NIST SP800-38D
- CCM: Counter with CBC-MAC mode defined by NIST SP800-38C
- CMAC: Cipher-based Message Authentication Code mode defined by NIST SP800-38B

### 42.3.4.4 Operation period

Below are the operation period counts for commonly used modes under each algorithm:

Table 42-5 AES Hardware Operation Period Count (Grouping size: 128-bit)

| Key length | ECB | CBC | CTR | CFB | OFB | CMAC | GCM |     |         |     | CCM |     |         |     |
|------------|-----|-----|-----|-----|-----|------|-----|-----|---------|-----|-----|-----|---------|-----|
|            |     |     |     |     |     |      | CFG | AAD | Enc/Dec | TAG | CFG | AAD | Enc/Dec | TAG |
| 128 bits   | 13  | 14  | 14  | 14  | 14  | 18   | 1   | 10  | 18      | 19  | 1   | 18  | 18      | 2   |
| 192 bits   | 15  | 16  | 16  | 16  | 16  | 20   | 1   | 10  | 20      | 21  | 1   | 20  | 20      | 2   |
| 256 bits   | 17  | 18  | 18  | 18  | 18  | 22   | 1   | 10  | 22      | 23  | 1   | 22  | 22      | 2   |

Table 42-6 SM4 Hardware Operation Period Number (Grouping size: 128-bit)

| Key length | ECB | CBC | CTR | CFB | OFB | GCM |     |         |     | CCM |     |         |     |
|------------|-----|-----|-----|-----|-----|-----|-----|---------|-----|-----|-----|---------|-----|
|            |     |     |     |     |     | CFG | AAD | Enc/Dec | TAG | CFG | AAD | Enc/Dec | TAG |
| 128 bits   | 36  | 37  | 37  | 37  | 37  | 1   | 10  | 41      | 42  | 1   | 41  | 41      | 2   |

Table 42-7 DES Hardware Operation Period Count (Grouping size: 64-bit)

| Key length | ECB | CBC | CTR | CFB | OFB |
|------------|-----|-----|-----|-----|-----|
| 64 bits    | 35  | 36  | 36  | 36  | 36  |

#### 42.3.4.5 Operating Procedures

The SKE decryption operation flow is as follows:

1. After power-on reset, SKE is idle, waiting to be called.
2. Determine whether the configuration in the SKE needs to be updated. If so, follow the configuration update procedure; otherwise, proceed directly to the data encryption/decryption process. If the configuration is not updated, the SKE will use the previously stored configuration for operations. Even if there is no switch key (KEY), initial value (IV) and other configurations, the configuration needs to be updated when switching data packets.
  - During Configuration Update:
    - a. Write the AAD length and ciphertext length to SKE\_AADx/SKE\_CLENx (applicable only in GCM/CCM mode).
    - b. Write the required configuration to SKE\_CFG, select encryption or decryption, and ensure that SKE\_CFG.UP\_CFG is 1.
    - c. Write the key to SKE\_KEYx. It is not necessary to input the key every time. If the key has already been written previously, there is no need to re-enter the same key. The SKE will use the previously stored key for computation.
    - d. The initial value is written through SKE\_IVx. In segmented interleaving for CCM, GCM, or CMAC modes, if operating in a middle or final segment, the intermediate values SKE\_MID\_MACx and SKE\_MID\_IVx must be provided.
    - e. Write 1 to SKE\_CTRL to trigger SKE to perform calculations.
    - f. Poll the flag bit corresponding to SKE\_SR2 until the flag bit is 1.
    - g. When the flag bit in SKE\_SR2 is detected to be 1, a write operation is performed on SKE\_SR2 to clear it.
    - h. Write 0 to SKE\_CFG.UP\_CFG; at this point, the configuration update process ends.
  - When encrypting and decrypting data:
    - a. (Optional) When AAD is input (only applicable in GCM/CCM mode), the following steps need to be performed:
      - 1) Make sure SKE\_DIN\_CR.LAST=0b0 and input the first set of AAD by writing to register SKE\_DINx.
      - 2) Write 1 to SKE\_CTRL to trigger SKE to perform calculations.
      - 3) Poll the flag bit corresponding to SKE\_SR2 until the flag bit is 1.
      - 4) When the flag bit in SKE\_SR2 is detected to be 1, a write operation is performed on SKE\_SR2 to clear it.
      - 5) Repeat steps 1) to 4). When inputting the last set of AAD, write SKE\_DIN\_CR.LAST=0b1 and then repeat steps 1) to 4).
    - b. Make sure SKE\_DIN\_CR.LAST=0b0.
    - c. By writing register SKE\_DINx, input the next set of data to be encrypted/decrypted.
    - d. Write 1 to SKE\_CTRL.START to trigger SKE to perform calculations.
    - e. Poll the SKE\_SR2.DONE flag until it is 1.
    - f. When SKE\_SR2.DONE is detected to be 1, the flag is cleared.
    - g. Repeat steps c-f. Note: If you are entering the last set of data and it is GCM/CCM/CMAC mode, you need to set SKE\_DIN\_CR.LAST=0b1 before entering the data.
    - h. After the last set of data encryption/decryption is completed, make sure SKE\_DIN\_CR.LAST=0b0.

- i. Read SKE\_DOUT to obtain the operation result; if it is the initial segment or middle segment of segmented interleaving, SKE\_MID\_MACx and SKE\_MID\_IVx need to be read; if TAG needs to be generated, repeat steps b-e again and read SKE\_DOUTx.

At this point, SKE has completed a complete call and can loop the above steps to make multiple calls.

#### 42.3.4.6 Register Address Mapping

SKE's SKE\_KEYx, SKE\_IVx, SKE\_DINx, SKE\_DOUTx, SKE\_MID\_IVx, and SKE\_MID\_MACx registers all use little-endian storage. The SKE\_KEYx register is used as an example as follows. Other registers are similar:

- DES 64-bit key length: 0x00, 0x01, 0x02, 0x03, 0x04, 0x05, 0x06, 0x07

| Register | Write Value |
|----------|-------------|
| SKE_KEY1 | 0x03020100  |
| SKE_KEY2 | 0x07060504  |

- AES 128-bit key length: 0x00, 0x01, 0x02, 0x03, 0x04, 0x05, 0x06, 0x07, 0x08, 0x09, 0x0A, 0x0B, 0x0C, 0x0D, 0x0E, 0x0F

| Register | Write Value |
|----------|-------------|
| SKE_KEY1 | 0x03020100  |
| SKE_KEY2 | 0x07060504  |
| SKE_KEY3 | 0x0B0A0908  |
| SKE_KEY4 | 0x0F0E0D0C  |

- AES 192-bit key length: 0x00, 0x01, 0x02, 0x03, 0x04, 0x05, 0x06, 0x07, 0x08, 0x09, 0x0A, 0x0B, 0x0C, 0x0D, 0x0E, 0x0F, 0x10, 0x11, 0x12, 0x13, 0x14, 0x15, 0x16, 0x17

| Register | Write Value |
|----------|-------------|
| SKE_KEY1 | 0x03020100  |

#### 42.3.4.8 Interrupt

SKE contains 1 interrupt. When the encryption and decryption operation of SKE is completed, the SKE\_SR2.SKE\_DONE flag is set to 1. If SKE\_CFG.IRQEN=1 at this time, an interrupt signal is generated. The SKE\_SR2.SKE\_DONE flag bit can be cleared by software.

## 42.4 Register Description

### 42.4.1 Register List

HASH base address: 0x40008400

Table 42-13 Secure Hash Algorithm (HASH) Register Offset

| Offset            | Register                 | Description                     | Width |
|-------------------|--------------------------|---------------------------------|-------|
| 0x0000            | <a href="#">HASH_CR</a>  | HASH Control Register           | 32    |
| 0x0010+0x4*(7-n)  | <a href="#">HASH_HRn</a> | HASH Summary Register n (n=0-7) | 32    |
| 0x0040+0x4*(15-n) | <a href="#">HASH_DRn</a> | HASH Data Register n (n=0-15)   | 32    |

TRNG base address: 0x40042000

Table 42-14 True Random Number Generator (TRNG) Register Offset

| Offset       | Register                 | Description                  | Width |
|--------------|--------------------------|------------------------------|-------|
| 0x0000       | <a href="#">TRNG_CR</a>  | TRNG Control Register        | 32    |
| 0x0004       | <a href="#">TRNG_MR</a>  | TRNG Mode Register           | 32    |
| 0x000C+0x4*n | <a href="#">TRNG_DRn</a> | TRNG Data Register n (n=0-1) | 32    |

PKE base address: 0x4000B000

Table 42-15 Public Key Engine (PKE) Register Offset

| 0   | START           | Start                         | 0b0: The module operation is finished or not started<br>0b1: Start the module for operation                                                                                                                                                                                                   | RW     |

**Note**

- The operation method of the START bit is: after the software writes 1 to this bit, the module will start to run; after the end of this run, the hardware will automatically clear this bit to 0; if the software queries this bit to 0, it means that this run is completed.
- The write operation to this register can only be performed when the module is not in the operation state (that is, when the START bit is 0), otherwise the hardware will automatically ignore the write operation. Read operations are not subject to this restriction.
- If you want to change the sequence of input data, you need to configure DATATYPE before inputting data.

#### 42.4.2.2 HASH Summary Register n (HASH\_HRn) (n=0-7)

The 8 HASH summary registers (HASH\_HR0-HASH\_HR7) correspond to 256-bit HASH summary. HASH\_HR0 corresponds to the summary Bit31-Bit0, HASH\_HR1 corresponds to the summary Bit63-Bit32, and so on.

Offset: 0x0010+0x4\*(7-n)

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| '      | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |

|------|------|---------------|--------------------------------------------------------------------------------------------------------------|--------|
| 31:0 | HASH | Summary Value | After the operation of the module is completed, the message summary can be obtained by reading this register | RO     |

#### Note

- This register is spliced by 8 32-bit registers. During the access, 8 32-bit registers are operated in turn, and the 32-bit register corresponding to the low address stores the high word of the message summary.
- The reading of this register can only be carried out when the module is not in the operation state (HASH\_CR.START=0), otherwise the reading of this register will get all 0.

42.4.2.3 HASH Data Register n (HASH\_DRn) (n=0-15)

16 HASH data registers (HASH\_DR0-HASH\_DR15) correspond to 512-bit HASH data. HASH\_DR0 corresponds to data Bit31-Bit0, HASH\_DR1 corresponds to data Bit63-Bit32, and so on.

Offset: 0x0040+0x4\*(15-n)

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| '      | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x00000000   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | DATA         |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Access | RW           |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| Bit  | Name | Function      | Description                                    | Access |
|------|------|---------------|------------------------------------------------|--------|
| 31:0 | DATA | Data register | Used to write messages before block operations | RW     |

 Note

- This register is spliced by 16 32-bit registers. During the access, 16 32-bit registers are operated in turn, and the 32-bit register corresponding to the low address stores the high word of the data.
- Writing to this register can only be performed when the module is not in the operation state (HASH\_CR.START=0), otherwise the hardware will automatically ignore the writing operation to this register.
- When this module is in operation state (HASH\_CR.START=1), reading this register will always result in all 0. In the non-operation state (HASH\_CR.START=0), the data read from this register (the data is the intermediate result of the calculation process) is arranged in the format of HASH\_CR.DATATYPE=0.

## 42.4.3 TRNG Register

42.4.3.3 TRNG Data Register n (TRNG\_DRn) (n=0-1)

2 TRNG data registers TRNG\_DR0-TRNG\_DR1 correspond to 64-bit TRNG data. TRNG\_DR0 corresponds to data Bit31-Bit0, TRNG\_DR1 corresponds to data Bit63-Bit32.

Offset: 0x000C+0x4\*n

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

**Note**

1. DATA\_TYPE is used to store the plaintext to be encrypted or the ciphertext to be decrypted in the SKE\_DIN register before the module operation, and the SKE\_DOUT register to store the encrypted ciphertext or decrypted plaintext after the operation is completed.

Data example: 0x11223344

| DATA_TYPE | Treatment of data | Usage data |
|-----------|-------------------|------------|
| 0x0       | No swap           | 0x11223344 |
| 0x1       | Halfword swap     | 0x33441122 |
| 0x2       | Byte swap         | 0x44332211 |
| 0x3       | Bit swap          | 0x22CC4488 |

## 42.4.5.3 SKE Status Register 1 (SKE\_SR1)

**Note**

Before triggering SKE calculation, you need to read the value of BUSY in this register first, and confirm that it is 0 before performing subsequent operations.

| 31:0 | TOTAL_C_LEN | Total bit length of Payload in data interleaving | This register is valid when SKE_CFG.SEC_STAGE=3.<br>Used in the final segment of GCM mode, it identifies the total length of data Payload. | RW     |

## 43 CRC Operation (CRC)

### 43.1 Introduction

In many applications, CRC algorithms are required to verify the integrity and correctness of data. Especially in data transmission, CRC checking is widely used. This module can use 11 algorithms, including CRC16/CCITT, CRC16/CCITT-FALSE, CRC16/XMODEM, CRC16/IBM, CRC16/MAXIM, CRC16/USB, CRC16/MODBUS, CRC16/X25, CRC32, CRC32/MPEG-2 and CRC64, to calculate and check the data.

### 43.2 Functional Description

#### 43.2.1 Function Block Diagram

Figure 43-1 CRC Application Diagram

#### 43.2.2 CRC Parameter Model

The CRC algorithm of this module complies with the definition of ISO/IEC13239, using 16-bit, 32-bit, and 64-bit CRC respectively. The corresponding parameter models for each CRC algorithm are shown in the table below.

Table 43-1 CRC Parameter Model

| CRC Algorithm Name | Polynomial Formula                                                                | Initial Value | Result XOR Value | Input Inversion | Output Inversion |
|--------------------|-----------------------------------------------------------------------------------|---------------|------------------|-----------------|------------------|
| CRC16/IBM          | $X^{16}+X^{15}+X^2+1$                                                             | 0x0000        | 0x0000           | Yes             | Yes              |
| CRC16/MAXIM        | $X^{16}+X^{15}+X^2+1$                                                             | 0x0000        | 0xFFFF           | Yes             | Yes              |
| CRC16/USB          | $X^{16}+X^{15}+X^2+1$                                                             | 0xFFFF        | 0xFFFF           | Yes             | Yes              |
| CRC16/MODBUS       | $X^{16}+X^{15}+X^2+1$                                                             | 0xFFFF        | 0x0000           | Yes             | Yes              |

The functions of this module include:

- CRC encoding and CRC check
- 3 bit width access methods: 8-bit, 16-bit, 32-bit:
  - ▶ Example of input data with 8-bit bit width: 0x00, 0x11, 0x22, 0x33, 0x44, 0x55, 0x66, 0x77;
  - ▶ Example of input data with 16-bit bit width: 0x1100, 0x3322, 0x5544, 0x7766;
  - ▶ Example of input data with 32-bit bit width: 0x33221100, 0x77665544.

### 43.2.3 CRC16 Encoding Mode

CRC encoding is the process of encoding the original data to calculate its CRC value. The operating procedures are as follows:

1. Write 0b0 to CRC\_CR.CR and write corresponding data to CRC\_CR.SELECT, selecting the corresponding CRC16 specification algorithm.
2. Initialize CRC calculation by writing 0x0000 or 0xFFFF to CRC\_RESULT1[15:0] according to the [CRC parameter model](#).
3. Organize the original data to be encoded into 8-bit/16-bit/32-bit formats and write them into CRC\_DAT register sequentially.

#### Note

When writing the CRC value in 8-bit format, write the low bits first and then the high bits.

4. Read CRC\_RESULT1[15:0] to obtain the 16-bit CRC encoded value.

### 43.2.4 CRC16 Check Mode

The check mode can verify whether the encoded data has been tampered. The operating procedures are as follows:

1. Write 0b0 to CRC\_CR.CR and write corresponding data to CRC\_CR.SELECT, selecting the corresponding CRC16 specification algorithm.
2. Initialize CRC calculation by writing 0x0000 or 0xFFFF to CRC\_RESULT1[15:0] according to the [CRC parameter model](#).
3. Write the encoded data into CRC\_DAT register sequentially in 8-bit, 16-bit, or 32-bit organization.

#### Note

When writing the CRC value in 8-bit format, write the low bits first and then the high bits.

4. Write the check code into the CRC\_DAT register with a 16-bit bit width.

**Note**

For CRC16/CCITT-FALSE and CRC16/XMODEM, the check code needs to be swapped between the high 8 bits and low 8 bits.

For example: 0x1234-> 0x3412

5. Read the value of CRC\_CR.FLAG. A value of 1 indicates check success, and a value of 0 indicates check failure.

### 43.2.5 CRC32 Encoding Mode

CRC encoding is the process of encoding the original data to calculate its CRC value. The operating procedures are as follows:

1. Write 0b1 to CRC\_CR.CR and write corresponding data to CRC\_CR.SELECT, selecting the corresponding CRC32 specification algorithm.
2. Write 0xFFFFFFFF to CRC\_RESULT1[31:0] to initialize CRC calculation.
3. Organize the original data to be encoded into 8-bit/16-bit/32-bit formats and write them into CRC\_DAT register sequentially.

**Note**

When writing the CRC value in 8-bit format, write the low bits first and then the high bits.

4. Read CRC\_RESULT1[31:0] to obtain the 32-bit CRC encoded value.

### 43.2.6 CRC32 Check Mode

The check mode can verify whether the encoded data has been tampered with. The operating procedures are as follows:

1. Write 0b1 to CRC\_CR.CR and write corresponding data to CRC\_CR.SELECT, selecting the corresponding CRC32 specification algorithm.
2. Write 0xFFFFFFFF to CRC\_RESULT1[31:0] to initialize CRC calculation.
3. Write the encoded data into CRC\_DAT register sequentially in 8-bit, 16-bit, or 32-bit organization.

**Note**

When writing the CRC value in 8-bit format, write the low bits first and then the high bits.

4. Write the check code into the CRC\_DAT register in 8-bit, 16-bit, or 32-bit organization.

**Note**

For CRC32/MPEG-2, during check, the high 16 bits and low 16 bits need to be swapped, and within each 16-bit section, the high 8 bits and low 8 bits also need to be swapped.

For example: 0x12345678->0x78563412

5. Read the value of CRC\_CR.FLAG. A value of 1 indicates check success, and a value of 0 indicates check failure.

### 43.2.7 CRC64 Encoding Mode

CRC encoding is the process of encoding the original data to calculate its CRC value. The operating procedures are as follows:

1. Write 0b1 to CRC\_CR.CR and write corresponding data to CRC\_CR.SELECT, selecting the corresponding CRC64 specification algorithm.

2. Write 0xFFFFFFFF to CRC\_RESULT1[31:0] and CRC\_RESULT2[31:0] to initialize CRC calculation.
3. Organize the original data to be encoded into 8-bit/16-bit/32-bit formats and write them into CRC\_DAT register sequentially.

**Note**

When writing the CRC value in 8-bit format, write the low bits first and then the high bits.

4. Read CRC\_RESULT1[31:0] and CRC\_RESULT2[31:0] to obtain the 64-bit CRC encoded value.

**Note**

CRC64\_DATA= {CRC\_RESULT2[31:0], CRC\_RESULT1[31:0]}.

### 43.2.8 CRC64 Check Mode

The check mode can verify whether the encoded data has been tampered. The operating procedures are as follows:

1. Write 0b1 to CRC\_CR.CR and write corresponding data to CRC\_CR.SELECT, selecting the corresponding CRC64 specification algorithm.
2. Write 0xFFFFFFFF to CRC\_RESULT1[31:0] and CRC\_RESULT2[31:0] to initialize CRC calculation.
3. Write the encoded data into CRC\_DAT register sequentially in 8-bit, 16-bit, or 32-bit organization.

**Note**

When writing the CRC value in 8-bit format, write the low bits first and then the high bits.

4. Write the check code into the CRC\_DAT register in 8-bit, 16-bit, or 32-bit organization.
5. Read the CRC\_CR.FLAG register. A value of 1 indicates check success, and a value of 0 indicates check failure.

### 43.3 Register Description

#### 43.3.1 Register List

Base address: 0x40008C00

Table 43-2 CRC Operation (CRC) Register Offset

| Offset    | Register    | Description           | Width |
|-----------|-------------|-----------------------|-------|
| 0x00      | CRC_CR      | CRC Control Register  | 32    |
| 0x04      | CRC_RESULT1 | CRC Result Register 1 | 32    |
| 0x08      | CRC_RESULT2 | CRC Result Register 2 | 32    |
| 0x80-0xFC | CRC_DAT     | CRC Data Register     | 32    |

| Name      | CRC_DAT      |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |  |  |  |  |  |  |
| Access    | RW           |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |  |  |  |  |  |  |

| Bit  | Name    | Function           | Description                                          | Access |
|------|---------|--------------------|------------------------------------------------------|--------|
| 31:0 | CRC_DAT | Data for operation | Write the data to be operated on; reads always as 0. | RW     |

**Note**

CRC\_DAT register is at the 0x80 offset from the CRC base address. The 0x84-0xFC offset from the base address are the mapping addresses of the CRC\_DAT register, with the same access and operation permissions as the CRC\_DAT register.

## 44 Data Computing Unit (DCU)

### 44.1 Introduction

The Data Computing Unit (DCU) is a simple data processing block that does not rely on the CPU. Each DCU unit has three data registers capable of performing addition, subtraction, comparison, and window comparison functions on two data values. It can also provide continuously varying digital values to the DAC module through timer triggers to generate triangular and sawtooth wave outputs. This product is equipped with 8 DCU units.

### 44.2 Features

- Supports 4 types of data processing: addition, subtraction, comparison of 2 data values, and window comparison of 3 data values.
- Addition and subtraction operations are performed on data in the DATA0 and DATA1 registers, with results stored in DATA0. Simultaneously, the result is automatically halved, and the halved result is stored in DATA1.
- Addition and subtraction can be triggered by writing to the register or by events from other peripheral circuits.
- In comparison mode, two data values can be compared between DATA0 and DATA1 registers, as well as between DATA0 and DATA2 registers. Interrupt and flag bits can be generated when the comparison results meet the conditions of greater than, less than, or equal to.
- Compare mode can also be used for window comparison by setting DATA1 and DATA2 as the upper and lower limits of the window, and judging whether DATA0 is within or outside the window based on the comparison results between DATA0 and DATA1, and DATA0 and DATA2.
- Operations can be triggered by events from other peripheral circuits, and various interrupts and event signals can be generated based on the operation results. When other peripheral circuits with hardware trigger start function select DCU as the trigger source, the DCU generates an event signal to start the peripheral circuit's action.
- In the triangular wave output mode, a timer is used to trigger the generation of continuously increasing and decreasing digital quantities to the digital-to-analog conversion module (DAC), the latter can then convert these digital quantities into triangular wave output through digital-to-analog conversion
- In the incremental sawtooth wave output mode, a timer is used to trigger the generation of continuously increasing digital quantities to the digital-to-analog conversion module (DAC), the latter can then convert these digital quantities into incremental sawtooth wave outputs through digital-to-analog conversion
- In the decreasing sawtooth wave output mode, a timer is used to trigger the generation of continuously decreasing digital quantities to the digital-to-analog conversion module (DAC), the latter can then convert these digital quantities into decreasing sawtooth wave output through digital-to-analog conversion

### 44.3 Functional Description

#### 44.3.1 Addition Mode

The addition mode calculates the sum of DATA0 and DATA1, where DATA0 is used as the summand and DATA1 is used as the addend. Each write to the DATA1 register performs a  $\text{DATA0} + \text{DATA1}$  addition

operation, with the result stored in DATA0 and the result divided by 2 stored in DATA2. An interrupt and flag bit are generated when the result of DATA0 + DATA1 is greater than 0xFF (8-bit mode) or 0xFFFF (16-bit mode) or 0xFFFFFFFF (32-bit mode).

Application example of addition mode:

- Step1.** Set the DCU\_CTL control register to addition mode with a data width of 16-bit;
- Step2.** Select the interrupt generation condition in the DCU\_INTEVTSEL register;
- Step3.** Write 0xFF00 and 0x55 to DATA0 and DATA1, respectively. The calculation result is 0xFF55, which is saved in DATA0, and 0xFF55/2 is saved in DATA2;
- Step4.** Continue writing 0xFF to DATA1. At this point, the calculation result ( $0xFF55 + 0xFF > 0xFFFF$ ) overflows, generating a result flag. Reading the flag register DCU\_FLAG obtains the result flag;
- Step5.** Write to the flag reset register DCU\_FLAGCLR to clear the flag bit.

### 44.3.2 Subtraction Mode

The subtraction mode calculates the difference between DATA0 and DATA1, where DATA0 acts as the minuend and DATA1 acts as the subtrahend. Each write to the DATA1 register performs a DATA0-DATA1 subtraction operation. The subtraction result is stored in DATA0, and the result divided by 2 is stored in DATA2. An interrupt and flag bit are generated when the DATA0-DATA1 result is less than 0x0 (in 8-bit, 16-bit, or 32-bit mode).

### 44.3.3 Hardware Trigger Start Mode

The DCU can trigger and start operations according to events generated by peripheral circuits. When using hardware trigger start mode, first enable the peripheral circuit trigger function in the function clock control 0 register (FCG0). Each DCU unit can independently select trigger start signals from other peripheral circuit, when select start signals, writing the peripheral circuit source number in the trigger source selection register (DCU\_TRGSEL). For details of the registers, please refer to the Automatic Operation System (AOS). When the peripheral circuit event occurs, the event signal is input to the DCU to trigger the DCU start operation.

Hardware trigger start mode includes trigger plus mode and trigger minus mode:

- In trigger plus mode, each event trigger initiates a DATA0+DATA1 addition. The result is stored in DATA0, and the result divided by 2 is stored in DATA2. If the result exceeds 0xFF (8-bit mode), 0xFFFF (16-bit mode), or 0xFFFFFFFF (32-bit mode), the flag bit is set and an interrupt is generated.
- In trigger minus mode, each trigger initiates a DATA0-DATA1 subtraction. The result is stored in DATA0, and the result divided by 2 is stored in DATA2. When the result of DATA0-DATA1 is less than 0x0 (in 8-bit, 16-bit, and 32-bit mode), the flag bit is set and an interrupt is generated.

Example application of hardware trigger start mode:

- Step1.** The control register DCU\_CTL selects the trigger plus mode, with a data width of 8-bit;
- Step2.** The interrupt condition selection register DCU\_INTEVTSEL selects the operation conditions;
- Step3.** Write 0x00 and 0x56 to DATA0 and DATA1 respectively;
- Step4.** Write the event number in the trigger source selection register DCU\_TRGSEL;
- Step5.** Make the selected peripheral circuit action and generate events, the DCU is triggered to perform an addition operation. The result is 0x56 and saved in DATA0, and 0x56 divided by 2 is saved in DATA2;
- Step6.** After three consecutive triggers, the calculation result overflows, generating a result flag. Reading the flag register DCU\_FLAG obtains the result flag;
- Step7.** Write to the flag reset register DCU\_FLAGCLR to clear the flag bit.

Figure 44-1 Hardware Trigger Start Schematic Diagram

#### 44.3.4 Comparative Mode

Comparing the size of DATA0 and DATA1 and DATA0 and DATA2, it can select when DATA0 is greater than DATA1, DATA0 is less than DATA1, DATA0 is equal to DATA1 and when DATA0 is greater than DATA2, DATA0 is less than DATA2, DATA0 is equal to DATA2, generate a flag and generate an interrupt. In the comparative mode, it can choose the conditions for data comparison, compare after writing DATA0 or write any data register.

Comparative mode application example:

- Step1.** Select comparative mode in the control register DCU\_CTL, with data width of 16-bit. Start comparison after writing to DATA0;
- Step2.** In the interrupt condition selection register DCU\_INTEVTSEL, select to generate a flag when DATA0>DATA1;
- Step3.** Write 0xB BBBB and 0xA AAAA to DATA1 and DATA0 respectively. Since DATA0>DATA1 is not satisfied, no flag is generated;
- Step4.** Write 0x8888 to DATA1. Although DATA0>DATA1 is now satisfied, since it's set to start comparison after writing to DATA0, no flag is generated;
- Step5.** After writing 0x9999 to DATA0, the flag generation condition is met, and a flag is generated;
- Step6.** Write to the flag reset register DCU\_FLAGCLR to clear the flag bit.

#### 44.3.5 Triangle Wave Output Mode

Triangle wave output mode is where DCU uses a timer as the trigger source to provide a continuously changing digital value for the Digital-to-Analog Converter (DAC), which converts these digital values into a triangle wave output. Triangle wave output mode is set through the DCU control register (DCU\_CTL). After setting to triangle wave output mode, the functions of data registers DATA0-2 will change. The data register DATA0 will serve as the data register for the digital values output to the DAC and be reset. DATA0 becomes the output data register, with DATA.DO (Bit0-Bit11) as active bits. DATA1 becomes the amplitude setting register, with DATA1.UPL (Bit16-Bit27) and DATA1.LWL (Bit0-Bit11) as active bits. DATA2 becomes the step setting register, with DATA2.STEP (Bit0-Bit11) as active bits.

#### Note

Only DCU1-4 support triangle wave output mode.

Steps for using triangle wave output mode:

- Step1.** Set the MODE in DCU control register (DCU\_CTL) to 0b1000;
- Step2.** Set the upper and lower limits of the triangle wave amplitude. The upper limit is set by DATA1.UPL[11:0] bit, and the lower limit is set by DATA1.LWL[11:0];
- Step3.** Set the step values for triangle wave increment and decrement through DATA2.STEP[11:0];
- Step4.** Select an appropriate timer event or software trigger as the trigger source through the trigger source selection register (DCU\_TRGSEL);
- Step5.** Configure the selected timer to generate trigger events at set time intervals;
- Step6.** Start the timer. On the first trigger event, the value of DATA1.LWL is loaded into DATA0.DO and output to DAC. Each time a trigger event occurs in the future, DATA0.DO will increment according to the step value set in DATA2.STEP;
- Step7.** When DATA0.DO increments to the upper limit set by DATA1.UPL, it will automatically start to decrement according to the step value set in DATA2.STEP. When it decrements to the lower limit set by DATA1.LWL, it starts to increment again;
- Step8.** If an interrupt is required when the triangle wave reaches its peak or valley, first set the interrupt enable bit (INTEN) in the DCU control register (DCU\_CTL) to inactive, then set the values of DATA0-DATA2. Clear the DCU flag bit once before starting the timer to generate trigger events, then set the interrupt enable bit (INTEN) in the DCU control register to active before starting the timer;
- Step9.** Set the MODE in DCU control register (DCU\_CTL) to 0b0000 to exit triangle wave output mode.

Figure 44-2 Triangular Wave Output Mode Waveform

Figure 44-3 Triangular Wave Output Mode

### 44.3.6 Increment Sawtooth Wave Output Mode

Increment sawtooth wave output mode is where DCU uses a timer as the trigger source to provide a continuously changing digital value for the Digital-to-Analog Converter (DAC), which converts these digital values into a sawtooth wave output. Increment sawtooth wave output mode is set through the DCU control register (DCU\_CTL). After setting to increment sawtooth wave output mode, the functions of data registers DATA0-2 will change. The data register DATA0 will serve as the data register for the digital values output to the DAC and be reset. DATA0 becomes the output data register, with DATA.DO (Bit0-Bit11) as active bits. DATA1 becomes the amplitude setting register, with DATA1.UPL (Bit16-Bit27) and DATA1.LWL (Bit0-Bit11) as active bits. DATA2 becomes the step setting register, with DATA2.STEP (Bit0-Bit11) as active bits.

#### Note

Only DCU1-4 support increment sawtooth wave output mode.

Steps for using increment sawtooth wave output mode:

- Step1.** Set the MODE in DCU control register (DCU\_CTL) to 0b1001;
- Step2.** Set the upper and lower limits of the sawtooth wave amplitude. The upper limit is set by DATA1.UPL[11:0] bit, and the lower limit is set by DATA1.LWL[11:0];
- Step3.** Set the increment step value of the sawtooth wave through DATA2.STEP[11:0];
- Step4.** Select an appropriate timer event or software trigger as the trigger source through the trigger source selection register (DCU\_TRGSEL);
- Step5.** Configure the selected timer to generate trigger events at set time intervals;
- Step6.** Start the timer. On the first trigger event, the value of DATA1.LWL is loaded into DATA0.DO and output to DAC. Each time a trigger event occurs in the future, DATA0.DO will increment according to the step value set in DATA2.STEP;
- Step7.** When DATA0.DO increments to the upper limit set by DATA1.UPL, it will automatically reload DATA1.LWL to DATA0.DO, making it start incrementing again from the lower limit set by DATA1.LWL;
- Step8.** If an interrupt is required when the sawtooth wave reloads, first set the interrupt enable bit (INTEN) in the DCU control register (DCU\_CTL) to inactive, then set the values of DATA0-DATA2. Clear the DCU flag bit once before starting the timer to generate trigger events, then set the interrupt enable bit (INTEN) in the DCU control register to active before starting the timer;
- Step9.** Set the MODE in DCU control register (DCU\_CTL) to 0b0000 to exit sawtooth wave output mode.

Figure 44-4 Incremental Sawtooth Wave Output Mode Waveform

Figure 44-5 Incremental Sawtooth Wave Output Mode

### 44.3.7 Decrement Sawtooth Wave Output Mode

Decrement sawtooth wave output mode is where DCU uses a timer as the trigger source to provide a continuously changing digital value for the Digital-to-Analog Converter (DAC), which converts these digital values into a sawtooth wave output. Decrement sawtooth wave output mode is set through the DCU control register (DCU\_CTL). After setting to decrement sawtooth wave output mode, the functions of data registers DATA0-2 will change. The data register DATA0 will serve as the data register for the digital values output to the DAC and be reset. DATA0 becomes the output data register, with DATA.DO (Bit0-Bit11) as active bits. DATA1 becomes the amplitude setting register, with DATA1.UPL (Bit16-Bit27) and DATA1.LWL (Bit0-Bit11) as active bits. DATA2 becomes the step setting register, with DATA2.STEP (Bit0-Bit11) as active bits.

#### Note

Only DCU1-4 support decrement sawtooth wave output mode.

Steps for using decrement sawtooth wave output mode:

- Step1.** Set the MODE in DCU control register (DCU\_CTL) to 0b1010;
- Step2.** Set the upper and lower limits of the sawtooth wave amplitude. The upper limit is configured via DATA1.UPL[11:0], and the lower limit is configured via DATA1.LWL[11:0];
- Step3.** Set the decrement step value of the sawtooth wave through DATA2.STEP[11:0];
- Step4.** Select an appropriate timer event or software trigger as the trigger source through the trigger source selection register (DCU\_TRGSEL);
- Step5.** Configure the selected timer to generate trigger events at set time intervals;
- Step6.** Start the timer. On the first trigger event, the value of DATA1.UPL is loaded into DATA0.DO and output to DAC. Each time a trigger event occurs in the future, DATA0.DO will decrement according to the step value set in DATA2.STEP;
- Step7.** When DATA0.DO decrements to the lower limit set by DATA1.LWL, it will automatically reload DATA1.UPL to DATA0.DO, making it start decrementing again from the upper limit set by DATA1.UPL;
- Step8.** If an interrupt is required when the sawtooth wave reloads, first set the interrupt enable bit (INTEN) in the DCU control register (DCU\_CTL) to inactive, then set the values of DATA0-DATA2.

Clear the DCU flag bit once before starting the timer to generate trigger events, then set the interrupt enable bit (INTEN) in the DCU control register to active before starting the timer;

- Step9.** Set the MODE in DCU control register (DCU\_CTL) to 0b0000 to exit sawtooth wave output mode.

Figure 44-7 Decrement Sawtooth Wave Output Mode

### 44.3.8 Interrupt and Event

DCU has various interrupts and event outputs for triggering other peripheral circuits for user selection. The control of interrupts and event outputs is managed by the interrupt and event register (DCU\_INTEVTSEL). When an event signal needs to be output, users need to set the corresponding control bit in the interrupt and event register (DCU\_INTEVTSEL) to active. Each DCU unit outputs a DCU event signal, respectively DCU1-DCU8 in the event list. When a corresponding event needs to generate an interrupt, users need to set the corresponding control bit in the interrupt and event register (DCU\_INTEVTSEL) to active, and simultaneously set the DCU\_CTL.INTEN bit in the control register to 1. Each DCU unit outputs a DCU interrupt signal, respectively DCU1-DCU8 in the interrupt list.

## 44.4 Register Description

### 44.4.1 Register List

- DCU1 base address: 0x40056000
- DCU2 base address: 0x40056400
- DCU3 base address: 0x40056800
- DCU4 base address: 0x40056C00
- DCU5 base address: 0x40057000
- DCU6 base address: 0x40057400
- DCU7 base address: 0x40057800
- DCU8 base address: 0x40057C00

Table 44-1 Data Computing Unit (DCU) Register Offset

| Offset      | Register      | Description                                  | Width |
|-------------|---------------|----------------------------------------------|-------|
| 0x00        | DCU_CTL       | DCU Control Register                         | 32    |
| 0x04        | DCU_FLAG      | DCU Flag Register (DCU1-DCU4)                | 32    |
| 0x04        | DCU_FLAG      | DCU Flag Register (DCU5-DCU8)                | 32    |
| 0x08+0x04*x | DCU_DATAx     | DCU Data Register x (x=0-2)                  | 32    |
| 0x14        | DCU_FLAGCLR   | DCU Flag Reset Register (DCU1-DCU4)          | 32    |
| 0x14        | DCU_FLAGCLR   | DCU Flag Reset Register (DCU5-DCU8)          | 32    |
| 0x18        | DCU_INTEVTSEL | DCU Interrupt and Event Register (DCU1-DCU4) | 32    |
| 0x18        | DCU_INTEVTSEL | DCU Interrupt and Event Register (DCU5-DCU8) | 32    |

#### 44.4.2 DCU Control Register (DCU\_CTL)

This register is used to configure the action mode of DCU.

| Offset | Bit Position |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |         |          |   |          |      |   |   |   |   |   |
|--------|--------------|----------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---------|----------|---|----------|------|---|---|---|---|---|

| 11    | FLAG_TOP | Triangle wave peak points   | In triangle wave output mode, when the value of DATA0[11:0] reaches the maximum, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_TOP bit is written as 1.                                                                                                               | RO     |
| 10    | FLAG_BTM | Triangle wave valley points | In triangle wave output mode, when the value of DATA0[11:0] reaches the minimum, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_TOP bit is written as 1.                                                                                                               | RO     |
| 9     | FLAG_RLD | Sawtooth wave reload        | In increment sawtooth wave output mode, when the value of DATA0[11:0] reaches the maximum, the bit is set; in decrement sawtooth wave output mode, when the value of DATA0[11:0] reaches the minimum, the bit is set. It cleared when DCU_FLAGCLR.CLR_RLD bit is written as 1. | RO     |
| 8:7   | Reserved | Reserved                    | -                                                                                                                                                                                                                                                                              | -      |
| 6     | FLAG_GT1 | Greater than flag bit 1     | In comparison mode, the flag is set when DATA0 > DATA1, and the flag is cleared when the DCU_FLAGCLR.CLR_GT1 bit is written as 1.                                                                                                                                              | RO     |
| 5     | FLAG_EQ1 | Equal flag bit 1            | In comparative mode, when DATA0=DATA1, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_EQ1 bit is written as 1.                                                                                                                                                         | RO     |
| 4     | FLAG_LS1 | Less than flag bit 1        | In comparative mode, when DATA0<DATA1, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_LS1 bit is written as 1.                                                                                                                                                         | RO     |
| 3     | FLAG_GT2 | Greater than flag bit 2     | In comparison mode, the flag is set when DATA0 > DATA2, and the flag is cleared when the DCU_FLAGCLR.CLR_GT2 bit is written as 1.                                                                                                                                              | RO     |
| 2     | FLAG_EQ2 | Equal flag bit 2            | In comparative mode, when DATA0=DATA2, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_EQ2 bit is written as 1.                                                                                                                                                         | RO     |

| Bit | Name     | Function             | Description                                                                                                                                                                                                                     | Access |
|-----|----------|----------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 1   | FLAG_LS2 | Less than flag bit 2 | In comparative mode, when $DATA0 < DATA2$ , the bit is set. It is cleared when the DCU_FLAGCLR.CLR_LS2 bit is written as 1.                                                                                                     | RO     |
| 0   | FLAG_OP  | Operation flag bit   | In addition/subtraction and trigger addition/trigger subtraction modes, when addition produces an overflow or subtraction produces an underflow, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_OP bit is written as 1. | RO     |

#### 44.4.4 DCU Flag Register (DCU\_FLAG) (DCU5-DCU8)

This register generates the DCU result identifier.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |          |    |          |    |          |    |          |    |          |  |          |  |

| 31:7 | Reserved | Reserved                | -                                                                                                                                                                                                                               | -      |
| 6    | FLAG_GT1 | Greater than flag bit 1 | In comparison mode, the flag is set when DATA0 > DATA1, and the flag is cleared when the DCU_FLAGCLR.CLR_GT1 bit is written with 1.                                                                                             | RO     |
| 5    | FLAG_EQ1 | Equal flag bit 1        | In comparative mode, when DATA0=DATA1, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_EQ1 bit is written as 1.                                                                                                          | RO     |
| 4    | FLAG_LS1 | Less than flag bit 1    | In comparative mode, when DATA0<DATA1, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_LS1 bit is written as 1.                                                                                                          | RO     |
| 3    | FLAG_GT2 | Greater than flag bit 2 | In comparison mode, the flag is set when DATA0 > DATA2, and the flag is cleared when the DCU_FLAGCLR.CLR_GT2 bit is written with 1.                                                                                             | RO     |
| 2    | FLAG_EQ2 | Equal flag bit 2        | In comparative mode, when DATA0=DATA2, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_EQ2 bit is written as 1.                                                                                                          | RO     |
| 1    | FLAG_LS2 | Less than flag bit 2    | In comparative mode, when DATA0<DATA2, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_LS2 bit is written as 1.                                                                                                          | RO     |
| 0    | FLAG_OP  | Operation flag bit      | In addition/subtraction and trigger addition/trigger subtraction modes, when addition produces an overflow or subtraction produces an underflow, the bit is set. It is cleared when the DCU_FLAGCLR.CLR_OP bit is written as 1. | RO     |

#### 44.4.5 DCU Data Register (DCU\_DATAx) (x=0-2)

The functions of each data register in different modes are as follows:

| Mode Functions                         | DATA0           | DATA1              | DATA2              |
|----------------------------------------|-----------------|--------------------|--------------------|
| Addition mode                          | Summand/Result  | Addend             | Halving result     |
| Trigger addition mode                  | Summand/Result  | Addend             | Halving result     |
| Subtraction mode                       | Minuend/Result  | Subtrahend         | Halving result     |
| Trigger subtraction mode               | Minuend/Result  | Subtrahend         | Halving result     |
| Compare mode                           | Compared object | Compare object 1   | Compare object 2   |
| Compare mode (window compare)          | Compared object | Window upper limit | Window lower limit |
| Triangular wave output mode*           | Output data     | Amplitude setting  | Step size          |
| Incremental sawtooth wave output mode* | Output data     | Amplitude setting  | Step size          |
| Decrement sawtooth wave output mode*   | Output data     | Amplitude setting  | Step size          |

#### Note

\*: Only DCU1/DCU2/DCU3/DCU4 supports this function.

Offset: 0x08+0x04\*x

#### Addition/Subtraction Mode, Trigger Addition/Subtraction Mode, Comparative Mode

This register is used to store operation data.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| '      | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x00000000   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | DAT          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Access | RW           |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| Bit  | Name | Function       | Description                                                                                                                                                                                                                                                                                                                       | Access |
|------|------|----------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------|
| 31:0 | DAT  | Operation data | Store operation data, the actual number of bits used depends on DCU_CTL.DATASIZE setting: <ul style="list-style-type: none"> <li>When DCU_CTL.DATASIZE=0b00, DATA[7:0] are valid data;</li> <li>When DCU_CTL.DATASIZE=0b01, DATA[15:0] are valid data;</li> <li>When DCU_CTL.DATASIZE=0b10, DATA[31:0] are valid data.</li> </ul> | RW     |

### Triangular Wave Output Mode

The register DCU\_DATA0 serves as the output data register, with Bit0-Bit11 as active bits.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| -      | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x00000000   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | Reserved     |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    | DO |    |   |   |   |   |   |   |   |   |   |   |
| Access |              |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    | RW |    |   |   |   |   |   |   |   |   |   |   |

| Bit   | Name     | Function    | Description        | Access |
|-------|----------|-------------|--------------------|--------|
| 31:12 | Reserved | Reserved    | -                  | -      |
| 11:0  | DO       | Output data | Data output to DAC | RW     |

The register DCU\_DATA1 serves as the amplitude setting register, with Bit16-Bit27 and Bit0-Bit11 as active bits.

| Offset | Bit Position |    |    |    |     |    |    |    |    |    |    |    |    |    |    |    |          |    |    |    |     |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|-----|----|----|----|----|----|----|----|----|----|----|----|----------|----|----|----|-----|----|---|---|---|---|---|---|---|---|---|---|
| -      | 31           | 30 | 29 | 28 | 27  | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15       | 14 | 13 | 12 | 11  | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x00000000   |    |    |    |     |    |    |    |    |    |    |    |    |    |    |    |          |    |    |    |     |    |   |   |   |   |   |   |   |   |   |   |
| Name   | Reserved     |    |    |    | UPL |    |    |    |    |    |    |    |    |    |    |    | Reserved |    |    |    | LWL |    |   |   |   |   |   |   |   |   |   |   |
| Access |              |    |    |    | RW  |    |    |    |    |    |    |    |    |    |    |    |          |    |    |    | RW  |    |   |   |   |   |   |   |   |   |   |   |

| Bit   | Name     | Function              | Description                                    | Access |

## 45 Math Arithmetical Unit (MAU)

### 45.1 Introduction

Math Arithmetical Unit (MAU) is a hardware accelerated operation module which contains two types of operations: root operation and sine operation, and supports root operation and sine operation of fixed points. The sine function supports  $360^\circ/2^{12}$  calculation accuracy.

### 45.2 Functional Description

#### 45.2.1 Square Root Operation

The square root operation supports 32-bit fixed-point input and outputs a 32-bit fixed-point result. The execution period varies depending on the input data value.

##### Operating Procedures

When the interrupt is disabled (MAU\_CSR.INTEN=0), the square root operation follows the steps below. When the interrupt is enabled, users may customize the process by adding interrupt handling:

- Step1.** Write the radicand (number to be square-rooted) into MAU\_DTR0 register;
- Step2.** Set the MAU\_CSR.START bit to 1 to trigger the operation;
- Step3.** The MAU\_CSR.BUSY bit will be set during computation. When the calculation is complete, this bit is automatically cleared; Wait until the BUSY bit is cleared, indicating the computation has completed;
- Step4.** Read the result from MAU\_RTR0 register;
- Step5.** Repeat steps 1-4 as needed.

Note: In step 3, after setting the MAU\_CSR.START bit, the BUSY bit rises and remains high for 8 to 16 calculation clock periods, then automatically goes to 0, with the calculation time varying depending on the input data size. Users can monitor this bit to track computation status. When using the square root operation module, users can flexibly judge the current operation status according to the changes of this bit.

##### Result Handling

The result of the square root operation is a 32-bit value. The least significant bit is rounded to the nearest integer using the "round half up" method.

For example: Input=0x0000000C → Output=0x00000003; Input=0x0000000D → Output=0x00000004.

##### Fixed-Point Number Processing

When using fixed-point decimal input and needing consistent formatting between input and output, users can configure the MAU\_CSR.SHIFT bit to adjust the output accordingly.

For example, when using the Q14.2 format for fixed-point arithmetic, you can set MAU\_CSR.SHIFT=1 so that the output results also follow the Q14.2 format. The fixed-point number 6.25 (0x00000019 in Q14.2 format) has an output result of 5 (0x00000005) before shifting, and a result of 2.5 (0x0000000A in Q14.2 format) after shifting 1 bit.

**Note**

When the exponent data written to MAU\_DTR0 is greater than 0xFFFF0000, the maximum value of MAU\_CSR.SHIFT can be set to 15; when the exponent data written to MAU\_DTR0 is less than or equal to 0xFFFF0000, the maximum value of MAU\_CSR.SHIFT can be set to 16.

### 45.2.2 Sine Operation

The sine operation supports 12-bit data input and the operation result is a 16-bit signed number output. The 12-bit data input represents the rectangular coordinate system angle to be calculated; in the 16-bit data output, the highest bit represents the positive or negative sign of the result.

Figure 45-1 Schematic Diagram Of Sine Operation Angle Value

### Operating Procedures

The operation flow of sine operation is as follows:

- Step1.** Write the angle value in MAU\_DTR1 register;
- Step2.** After 1 period, read the operation result from MAU\_RTR1 register;
- Step3.** Repeat the above steps 1-2.

### 45.2.3 Interrupt and Event Output

#### Interrupt Output

After each square root operation is completed, a corresponding operation completion event will be generated. If the interrupt control bit is enabled (MAU\_CSR.INTEN=1), the corresponding interrupt request signal (MAU\_SQRT) will also be generated.

#### Event Output

After each square root operation is completed, a corresponding operation completion event will be generated, and the corresponding event request signal (MAU\_SQRT) will also be output, which can be used to select and trigger other modules.

## 45.3 Register Description

### 45.3.1 Register List

Base address: 0x40055000

Table 45-1 Math Unit (MAU) Register Offset

| Offset | Register | Description              | Width |
|--------|----------|--------------------------|-------|
| 0x0000 | MAU_CSR  | Control Status Register  | 32    |
| 0x0004 | MAU_DTR0 | Data Input Register 0    | 32    |
| 0x000C | MAU_RTR0 | Result Output Register 0 | 32    |
| 0x0010 | MAU_DTR1 | Data Input Register 1    | 32    |
| 0x0014 | MAU_RTR1 | Result Output Register 1 | 32    |

## 45.3.2 Control State Register (MAU\_CSR)

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |       |    |    |    |          |    |   |   |      |   |          |   |       |   |       |   |

## 46 Filter Math Accelerator (FMAC)

### 46.1 Introduction

Filter Math Accelerator (FMAC) is a hardware acceleration module for FIR filter calculation. The module can carry out FIR digital filtering with a maximum of 16 orders and configurable orders. Built-in 16x16bits multiplier and 32+5bits adder, users can customize the output data precision. This series of products is equipped with 4 FMAC modules.

### 46.2 Features

- Maximum 16-order FIR filter, configurable order
- Configurable filter coefficients
- 16 -bit signed input and output data, 16 -bit signed filter coefficients
- 16x16bits multiplier
- 32+5bits adder
- Provide interrupt signal and status query
- AHB slave interface configuration parameters and input and output data

### 46.3 Functional Description

#### 46.3.1 Basic Block Diagram

Figure 46-1 FMAC Basic Block Diagram

When the 16th-order FIR filter is selected, the FMAC operation control and operation core requires 17 clock periods to process one data. At an operating clock frequency of 240MHz, it can process a maximum input data stream of 14.1MHz. Different orders require different processing times. The smaller the order, the faster the processing speed. The relationship between the maximum input data frequency, the order and the operating clock frequency is as follows:

Maximum input data frequency (MHz)=operating clock frequency (MHz) ÷(order + 1)

### 46.3.2 Operating Procedures

This module needs to be used according to the following steps:

- Step1.** Set the enable bit (FMAC\_ENR.FMACEN) to 1;
- Step2.** Configure the filtering order (FMAC\_CTR.STAGE\_NUM) and the number of shifts to output active results (FMAC\_CTR.SHIFT);
- Step3.** If you need to use interrupts, configure the interrupt enable bit (FMAC\_IER.INTEN) to 1;
- Step4.** Write filter coefficients (if there are N orders, just configure FMAC\_COR0-FMAC\_CORN);
- Step5.** Write data to be processed (FMAC\_DTR);
- Step6.** Wait for the completion interrupt or query the completion status (FMAC\_STR.READY) to be 1;
- Step7.** Read result (FAMC\_RTR0 or FAMC\_RTR1);
- Step8.** Repeat steps 5 to 7 until all data has been processed.

### 46.3.3 Module Enable

The module enable bit (FMAC\_ENR.FMACEN) has two functions. The first function is to enable the entire module. Only when it is 1, the module is enabled to work. The second function is the soft reset of the module. When a certain order and coefficient configuration is used up, it is necessary to change to another order and coefficient configuration. In this case, FMACEN needs to be set to 0, the residual information of the previous calculation is cleared, and then the operation is carried out according to the operation process.

FMACEN is reset to 0, the configuration parameters are not cleared, only the internal registers and intermediate results are cleared.

### 46.3.4 Coefficient Normalization

If the output result is only 16 bits, then the total number of bits truncated during the calculation process and the calculation result is as high as 20 bits. Therefore, if the input data involved in the calculation is too small, the output result may be 0 or a very small number (with a large loss of precision). Therefore, it is necessary to normalize the filter coefficients, that is, normalize the maximum value (if it is a positive number) to 32767 (if it is a negative number, normalize it to -32768 ), and multiply the other coefficients by the same ratio.

For example, there are 5 coefficients 10, 13, 35, 96, 42, and they need to be normalized. First find the maximum value, which is 96, and then divide 32767 by the maximum value,  $32767/96=341.3$ , and take the value 341, which is the normalized multiple. All other coefficients must be multiplied by this multiple to get the normalized number.

So the normalized coefficients are: 3410, 4433, 11935, 32736, 14322.

### 46.3.5 Interrupt and Events

#### 46.3.5.1 Interrupt Output

After each operation is completed, a corresponding operation completion event will be generated. If the interrupt control bit is enabled ( FMAC\_IER.INTEN=1 ), the corresponding interrupt request signal ( FMAC\_m\_FIR, m=1-4 ) will also be generated.

#### 46.3.5.2 Event Output

After each operation is completed, a corresponding operation completion event will be generated, and the corresponding event request signal (FMAC\_m\_FIR, m=1-4) will also be output, which can be used to select and trigger other modules.

## 46.4 Register Description

All registers cannot be read immediately after writing. When writing to a register, two HCLK periods are required to load it into the register.

### 46.4.1 Register List

- FMAC1 base address: 0x40058000
- FMAC2 base address: 0x40058400
- FMAC3 base address: 0x40058800
- FMAC4 base address: 0x40058C00

Table 46-1 Filter Math Accelerator (FMAC) Register Offset

| Offset        | Register  | Description                            | Width |
|---------------|-----------|----------------------------------------|-------|
| 0x0000        | FMAC_ENR  | Module Enable Register                 | 32    |

## 47 Error Management Unit (ERMU)

### 47.1 Introduction

Error Management Unit (ERMU) collects error notifications from the safety mechanisms of this product. Each error notification has three response behavior configurations: system interrupt, system reset, and output to the error output port to notify the system for further error handling operations.

### 47.2 Features

- Each error notification has three response behavior configurations: system interrupt, system reset, and output to the error output port
- Error output can be configured from the following three types
  - ▶ Single pin output
  - ▶ Single pin flip output
  - ▶ Dual pins complementary output
- Up to 4 groups of error output are supported
- Support pseudo-error source triggering for diagnosis and debugging
- Support response timeout function for error interrupt handling

## 47.3 Functional Description

### 47.3.1 Function Block Diagram

Figure 47-1 ERMU Block Diagram

Table 47-1 ERMU Parameter Definition Table

| Parameter Name | Value | Description                                                       |
|----------------|-------|-------------------------------------------------------------------|
| y              | 0-3   | Error output channel groups are identified by the number 'y'      |
| z              | 0-3   | Single wait timer is identified by the number 'z'                 |
| j              | 0-1   | Error source groups are identified by the number 'j'              |
| k              | 0-31  | Single error source in each group is identified by the number 'k' |
| i              | 0-63  | Single error source ID is identified by the number 'i'            |

#### Note

The content of this table applies to all sections of ERMU.

Table 47-2 ERMU Input/Output Ports

| Port Name                   | Port Type | Description                                                                                 |
|-----------------------------|-----------|---------------------------------------------------------------------------------------------|
| ERMU_EOU-TyM <sup>(1)</sup> | Output    | Error output forward port                                                                   |
| ERMU_EOUTyC                 | Output    | Error output reverse port, the output is reversed compared to the error output forward port |

**Note**

1. Among them, ERMU\_EOUT0M can be configured by ICG8 as the ERMU\_EOUT0M default output pin.
2. Except for 1, other error output ports can be selected for the corresponding functions through the port configuration register.

## 47.3.2 Error Output Channel

### 47.3.2.1 Error Output Operation

After reset release, the default ERMU\_EOyS.EOS is 1. Before using ERMU, ERMU\_EOyC.CLR needs to be written to clear ERMU\_EOyS.EOS. For the output level behavior of the output ports ERMU\_EOUTyM and ERMU\_EOUTyC during reset and after reset, refer to [Error Output Description](#).

In addition to the output ERMU\_EOUT0M of ERMU, which can be configured as the default output pin by ICG8, the other outputs ERMU\_EOUTyM and ERMU\_EOUTyC of ERMU need to be set to the corresponding port output functions to ERMU\_EOUTyM and ERMU\_EOUTyC before using ERMU. For specific configurations, see the "General-Purpose IO (GPIO) " chapter.

When the ERMU\_EOyS.EOS status changes, the levels of the outputs ERMU\_EOUTyM and ERMU\_EOUTyC of ERMU change accordingly. For details, see the following table.

Table 47-3 Error Output Operation

| Error Source Status ER-MU_ESSj.ESSk | Toggle Timer Enable | ERMU_EOUTyM Output Level <sup>(1)</sup> | ERMU_EOUTyC Output Level <sup>(1)</sup> | Error Output Status ER-MU_EOyS.EOS |
|-------------------------------------|---------------------|-----------------------------------------|-----------------------------------------|------------------------------------|
| 0                                   | 0(Disable)          | High                                    | Low                                     | 0 (No Error)                       |
|                                     | 1(Enable)           | Flip                                    | Flip                                    | 0 (No Error)                       |
| 1                                   | 0(Disable)          | Low                                     | High                                    | 1(Error Detected)                  |
|                                     | 1(Enable)           | Low                                     | High <sup>(2)</sup>                     | 1(Error Detected)                  |

**Note**

1. The output from the error source to the error port can be masked by ERMU\_EOyOMj. ERMU\_EOUT0M can be configured as the default output pin by ICG8. For the other output ports ERMU\_EOUTyM and ERMU\_EOUTyC, the corresponding port configuration register needs to be set by software to select the corresponding error output function of ERMU to act as the error output port.
2. Assuming that when the flip timer is enabled, ERMU\_EOUTyC is configured as the port output function.

### 47.3.2.2 Error Output Description

For the behavior of ERMU\_EOUTyM and ERMU\_EOUTyC during reset and after reset, see the following table.

Table 47-4 Description of ERMU\_EOUT0M Output Situation

| Categories                | Reset Category            |              |                            |                            |
|---------------------------|---------------------------|--------------|----------------------------|----------------------------|
|                           | Power-on/Power-down Reset | System Reset | Module Reset               | JTAG Reset                 |
| Output level during reset | Hi-Z                      | Hi-Z         | Retain output before reset | Retain output before reset |

| Categories               | Reset Category            |              |                            |                            |
|--------------------------|---------------------------|--------------|----------------------------|----------------------------|
|                          | Power-on/Power-down Reset | System Reset | Module Reset               | JTAG Reset                 |
| Output level after reset | Low level                 | Low level    | Retain output before reset | Retain output before reset |

Table 47-5 ERMU\_EOUTyM (y=1-3) and ERMU\_EOUTyC (y=0-3) Output Port Description

| Categories                | Reset Category            |                           |                            |                            |
|---------------------------|---------------------------|---------------------------|----------------------------|----------------------------|
|                           | Power-on/Power-down Reset | System Reset              | Module Reset               | JTAG Reset                 |
| Output level during reset | Hi-Z                      | Hi-Z                      | Retain output before reset | Retain output before reset |
| Output level after reset  | General IO <sup>(1)</sup> | General IO <sup>(1)</sup> | Retain output before reset | Retain output before reset |

**Note**

1. When the reset of the output ports ERMU\_EOUTyM (y=1-3) and ERMU\_EOUTyC (y=0-3) is released and it become general IO function. The corresponding port configuration register needs to be set by software to select the corresponding error output function of ERMU to act as the error output port.

### 47.3.2.3 Error Output Status is Controlled by Software

#### Set Error Output Status

Follow the steps below to set the error output status through software:

1. Set ERMU\_EOyC.SET to 1
2. Wait until ERMU\_EOyS.EOS becomes 1

#### Clear Error Output Status

Follow the steps below to clear the error output status:

1. Confirm that all ERMU\_ESSj.ESSk not masked by ERMU\_EOyOMj are 0
2. Wait for ERMU\_EOyS.CTS to become 0
3. Set ERMU\_EOyC.CLR to 1
4. Wait until ERMU\_EOyS.EOS becomes 0

### 47.3.2.4 Flip Timer

The flip timer count clock is the clock after the MRC (8MHz) is prescaled. If ERMU\_EOyTTC.TTE=1, the flip timer starts counting from 0, and when the counter value matches ERMU\_EOyTTCMP, it starts counting from 0 again. When the counter value matches, the output signals ERMU\_EOUTyM and ERMU\_EOUTyC are flipped.

### 47.3.2.5 Enable Flip Timer

Follow the steps below to enable the flip timer:

1. Set ERMU\_EOyTTCMP to define the flip period
2. Set ERMU\_EOyC.CLR to 1 to clear the error output status
3. Wait until ERMU\_EOyS.EOS becomes 0
4. Set ERMU\_EOyTTC.TTE to 1

#### 47.3.2.6 Disable Flip Timer

Follow the steps below to disable the flip timer:

1. Set `ERMU_EOyC.SET` to 1 to set the error output status
2. Wait until `ERMU_EOyS.EOS` becomes 1
3. Set `ERMU_EOyTTC.TTE` to 0

#### 47.3.2.7 Clear Timer

Use the clear timer to keep the error status output by the ERMU output port active for a certain time period, which can be configured through `ERMU_EOyCTCMP`.

The clear timer count clock is the clock after the MRC (8MHz) is prescaled. Set `ERMU_EOyCTCMP` to a non-zero value and `ERMU_EOyC.CTE=1` to enable the clear timer. When an active error source occurs, the counter starts counting. Note that even during the clear timer count process, when a new active error source appears, the counter starts counting from 0. When the counter value matches `ERMU_EOyCTCMP`, the clear timer stops counting. When `ERMU_EOyS.CTS=1`, writing 1 to `ERMU_EOyC.CLR` has no effect.

#### 47.3.3 Wait Timer

Use the wait timer to detect the processing time for the CPU to handle ERMU interrupts (high priority interrupts or low priority interrupts). Once a timeout is detected, further requests can be made for the port to output the error status or request a system reset.

The wait timer count clock is the clock after the MRC (8MHz) is prescaled. Set `ERMU_WTzCMP` to a non-zero value and `ERMU_WTzC.WTE=1` to enable the wait timer. When the start interrupt set by `ERMU_WTzSE` is enabled, the counter starts counting from 0. During the wait timer count process, the generation of new interrupts does not affect the wait timer count. When the counter value matches `ERMU_WTzCMP`, the wait timer stops counting and generates the corresponding wait timer timeout error signal `ERMU_WTzE`.

`ERMU_WTzE` can be configured as error output, interrupt, or reset request.

##### Notice

Avoid triggering the timeout event loop by itself for the same wait timer. This situation can be described as when the timeout event of the current stage wait timer occurs (that is, `ERMU_WTzE` is enable), and this signal is also configured as the start interrupt of the ERMU wait timer, triggering the wait timer to start counting for the next stage, and then the timeout event triggers itself in a loop. It is recommended to set `ERMU_WTzE` to different error notification types. For example, when the trigger source of `ERMU_WTzE` is `ERMU_LPI`, set the `ERMU_WTzE` event to the high priority interrupt `ERMU_HPI`; for another example, when the trigger source of `ERMU_WTzE` is `ERMU_HPI`, set the `ERMU_WTzE` event to the reset `ERMU_RST` or `EOUTyM`.

#### 47.3.4 Reset Request

When the enabled error source in `ERMU_REj` has an error, ERMU sends a reset request to the reset control module RMU, which eventually causes a system reset.

For the reset timing and reset flag, see "Reset Control (RMU) " chapter.

#### 47.3.5 Interrupt Request

When the enabled error source in `ERMU_HPIEj` or `ERMU_LPIEj` has an error, ERMU sends an `ERMU_HPI` request or an `ERMU_LPI` request. As a system non-maskable interrupt (NMI), `ERMU_HPI` directly causes a

system interrupt. ERMU\_LPI needs to set the corresponding enable register in INTC at the same time to cause an active system interrupt. For details, see "Interrupt Controller (INTC) " chapter.

### 47.3.6 Pseudo Error Trigger

The pseudo error source triggers ERMU\_PETj.PETk as a test or debugging methods. The error source error behavior can be injected by software. The processing of pseudo-error source error behavior in the ERMU module is basically the same as the processing when the real error source has an error.

### 47.3.7 Interrupt

ERMU supports interrupt requests from different events. The specific information is as follows:

| Interrupt Event              | Interrupt Flag | Interrupt Enable     | Description                                                       |
|------------------------------|----------------|----------------------|-------------------------------------------------------------------|
| ERMU high priority interrupt | ERMU_HPI       | Register ER-MU_HPIEj | Used as an NMI interrupt, directly output to the processor        |
| ERMU low priority interrupt  | ERMU_LPI       | Register ER-MU_LPIEj | Normal interrupt, output to the processor through the INTC module |

### 47.3.8 Error Source

ERMU supports requests from different error sources. The specific information is as follows:

Table 47-7 ERMU Error Source List

| ID    | Module | Name       | Description                   |
|-------|--------|------------|-------------------------------|
| 0     | ERMU   | ERMU_WT0E  | ERMU wait timer 0 error       |
| 1     | ERMU   | ERMU_WT1E  | ERMU wait timer 1 error       |
| 2     | ERMU   | ERMU_WT2E  | ERMU wait timer 2 error       |
| 3     | ERMU   | ERMU_WT3E  | ERMU wait timer 3 error       |
| 4-7   | -      | -          | Reserved                      |
| 8     | SWDT   | SWDT_ERR   | SWDT timeout overflow error   |
| 9     | WDT    | WDT_ERR    | WDT timeout overflow error    |
| 10    | -      | -          | Reserved                      |
| 11    | EFM    | FLASH_CERR | FLASH ECC correctable error   |
| 12    | EFM    | FLASH_FERR | FLASH ECC uncorrectable error |
| 13    | EFM    | FLASH_OERR | FLASH ECC overflow error      |
| 14    | SRAMH  | SRAMH_CERR | SRAMH ECC correctable error   |
| 15    | SRAM1  | SRAM1_CERR | SRAM1 ECC correctable error   |
| 16    | SRAM2  | SRAM2_CERR | SRAM2 ECC correctable error   |
| 17    | SRAM3  | SRAM3_CERR | SRAM3 ECC correctable error   |
| 18    | SRAM4  | SRAM4_CERR | SRAM4 ECC correctable error   |
| 19    | SRAMB  | SRAMB_CERR | SRAMB ECC correctable error   |
| 20-22 | -      | -          | Reserved                      |

| ID    | Module | Name                   | Description                       |
|-------|--------|------------------------|-----------------------------------|
| 23    | SRAMH  | SRAMH_FERR             | SRAMH ECC uncorrectable error     |
| 24    | SRAM1  | SRAM1_FERR             | SRAM1 ECC uncorrectable error     |
| 25    | SRAM2  | SRAM2_FERR             | SRAM2 ECC uncorrectable error     |
| 26    | SRAM3  | SRAM3_FERR             | SRAM3 ECC uncorrectable error     |
| 27    | SRAM4  | SRAM4_FERR             | SRAM4 ECC uncorrectable error     |
| 28    | SRAMB  | SRAMB_FERR             | SRAMB ECC uncorrectable error     |
| 29-31 | -      | -                      | Reserved                          |
| 32    | CACHE  | CACHE_CERR             | Cache RAM ECC correctable error   |
| 33    | CACHE  | CACHE_FERR             | Cache RAM ECC uncorrectable error |
| 34-35 | -      | -                      | Reserved                          |
| 36    | CAN1   | CREC1_CERR             | CAN1 RAM ECC correctable error    |
| 37    | CAN2   | CREC2_CERR             | CAN2 RAM ECC correctable error    |
| 38    | MCAN   | MCREC_CERR             | MCAN RAM ECC correctable error    |
| 39-41 | -      | -                      | Reserved                          |
| 42    | CAN1   | CREC1_FERR             | CAN1 RAM ECC uncorrectable error  |
| 43    | CAN2   | CREC2_FERR             | CAN2 RAM ECC uncorrectable error  |
| 44    | MCAN   | MCREC_FERR             | MCAN RAM ECC uncorrectable error  |
| 45-47 | -      | -                      | Reserved                          |
| 48    | PKE_LP | PKERAM_CERR            | PKE RAM ECC correctable error     |
| 49    | PKE_LP | PKERAM_FERR            | PKE RAM ECC uncorrectable error   |
| 50    | -      | -                      | Reserved                          |
| 51    | MPU    | MPU_SMPU1ERR           | MPU SMPU 1 bus error              |
| 52    | MPU    | MPU_SMPU2ERR           | MPU SMPU 2 bus error              |
| 53    | MPU    | MPU_FMPUERR            | MPU FMPU bus error                |
| 54    | MPU    | MPU_HMPUERR            | MPU HMPU bus error                |
| 55    | MPU    | MPU_EMPUERR            | MPU EMPU bus error                |
| 56    | -      | -                      | Reserved                          |
| 57    | DMA    | DMA1_ERR               | DMA1 transfer error               |
| 58    | DMA    | DMA2_ERR               | DMA2 transfer error               |
| 59    | -      | -                      | Reserved                          |
| 60    | INTC   | FPU_ERR <sup>(1)</sup> | FPU calculation error             |
| 61    | FCM    | FCM_ERR                | clock monitor error               |
| 62-63 | -      | -                      | Reserved                          |

**Note**

1. The FPU-related error interrupt needs to be enabled first, and the corresponding error can be output to ERMU when it occurs.

## 47.4 Operation Example

### 47.4.1 ERMU Error Management Example

#### Procedure

- Step1.** Read and check each bit in ERMU\_ESSj to confirm whether there is an error;
- Step2.** If there is an error, directly enter the system error handling program. If there is no error, enter the following process;
- Step3.** Write 1 to ERMU\_EOyC.CLR;
- Step4.** Read and check ERMU\_EOyS.EOS until it is 0. If it is not 0 all the time, go to Step1;
- Step5.** Set the port function register as needed to select the output functions of ERMU\_EOUTyM and ERMU\_EOUTyC;
- Step6.** Configure ERMU\_EOyOMj, ERMU\_HPIEj, ERMU\_LPIEj, and ERMU\_REj as required.
- Step7.** Set ERMU\_EOyCTCMP and ERMU\_EOyC.CTE as needed;
- Step8.** Configure ERMU\_EOyTTCMP and ERMU\_EOyTTC.TTE as required.
- Step9.** Configure ERMU\_WTzCMP, ERMU\_WTzSE, and ERMU\_WTzC.WTE as required.
- Step10.** Set the access permission of the ERMU bus, cancel the write permission, and only keep the read permission;
- Step11.** Configure the interrupt handling functions for ERMU\_HPI and ERMU\_LPI when interrupts occur as needed.

## 47.5 Register Description

### 47.5.1 Register List

Base address: 0x40048800

Table 47-8 Error Management Unit (ERMU) Register Offset

| Offset          | Register      | Description                                         | Width |
|-----------------|---------------|-----------------------------------------------------|-------|
| 0x0080*y        | ERMU_EOyC     | Error Output y Control Register (y=0-3)             | 32    |
| 0x0004+0x0080*y | ERMU_EOyS     | Error Output y Status Register (y=0-3)              | 32    |
| 0x0008+0x0080*y | ERMU_EOyCTCNT | Error Output y Clear Timer Count Register (y=0-3)   | 32    |
| 0x000C+0x0080*y | ERMU_EOyCTCMP | Error Output y Clear Timer Compare Register (y=0-3) | 32    |
| 0x0010+0x0080*y | ERMU_EOyTTC   | Error Output y Flip Timer Control Register (y=0-3)  | 32    |
| 0x0018+0x0080*y | ERMU_EOyTTCMP | Error output y Flip Timer Compare register (y=0-3)  | 32    |
| 0x0040+0x0080*y | ERMU_EOyOM0   | Error Output y Output Mask 0 Register (y=0-3)       | 32    |
| 0x0044+0x0080*y | ERMU_EOyOM1   | Error Output y Output Mask 1 Register (y=0-3)       | 32    |
| 0x0200+0x0020*z | ERMU_WTzC     | Wait Timer z Control Register (z=0-3)               | 32    |
| 0x0204+0x0020*z | ERMU_WTzS     | Wait Timer z Status Register (z=0-3)                | 32    |
| 0x0208+0x0020*z | ERMU_WTzCNT   | Wait Timer z Count Register (z=0-3)                 | 32    |
| 0x020C+0x0020*z | ERMU_WTzCMP   | Wait Timer z Compare Register (z=0-3)               | 32    |
| 0x0210+0x0020*z | ERMU_WTzSE    | Wait Timer z Start Enable Register (z=0-3)          | 32    |
| 0x0300+0x0004*j | ERMU_ESSj     | Error Source Status j Register (j=0-1)              | 32    |
| 0x0340+0x0004*j | ERMU_ESSCj    | Error Source Status Clear j Register (j=0-1)        | 32    |
| 0x0380+0x0004*j | ERMU_PETj     | Pseudo-error Source Trigger j Register (j=0-1)      | 32    |
| 0x03C0+0x0004*j | ERMU_REj      | Reset Enable j Register (j=0-1)                     | 32    |
| 0x0400+0x0004*j | ERMU_LPIEj    | Low-Priority Interrupt Enable j Register (j=0-1)    | 32    |
| 0x0500+0x0004*j | ERMU_HPIEj    | High-Priority Interrupt Enable j Register (j=0-1)   | 32    |
| 0x0600          | ERMU_CCPS     | Count Clock Prescaler Register                      | 32    |

#### Note

Write access to the ERMU register only supports word write mode.

## 47.5.2 Error Output y Control Register (ERMU\_EOyC) (y=0-3)

| Offset   | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |     |          |    |    |    |    |   |   |   |   |   |   |   |   |   |   |  |     |     |
|----------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|-----|----------|----|----|----|----|---|---|---|---|---|---|---|---|---|---|--|-----|-----|

## 48 Debug Controller (DBGC)

### 48.1 Introduction

This MCU's core is Cortex-M4, which includes hardware for advanced debugging functions and supports the Embedded Trace Macrocell (ETM). Using these debugging functions, the core can be stopped when fetching instructions (instruction breakpoint) or accessing data (data breakpoint). When the core is stopped, the internal state of the core and the external state of the system can be queried. After the query completes, the kernel and system are restored and program execution is restored.

**Two debugging interfaces are provided:**

- Serial debug trace interface SWD
- Parallel debug trace interface JTAG

### 48.2 Functional Description

#### 48.2.1 Function Block Diagram

Figure 48-1 Debug Control System Block Diagram

The ARM Cortex-M4 core provides integrated on-chip debugging support. It includes:

- SWJ-DP: SWD/ JTAG debug port
- AHB-AP: AHB access port
- ITM: Instruction tracking unit
- FPB: Flash instruction breakpoint
- DWT: Data breakpoint trigger
- TPIU: Trace port unit interface (available on larger packages where corresponding pins are mapped)
- Flexible debugging pin assignment

**Note**

For more information on the debugging functions supported by the ARM Cortex-M4 core, see the "Cortex-M4F-r0p1 Technical Reference Manual" and "CoreSight Design Kit r0p1 Technical Reference Manual".

## 48.2.2 Reference Documentation

This product references the following ARM technical documentation:

- Cortex M4 Technical Reference Manual r0p1
- Arm Debug Interface Architecture Specification version 5
- CoreSight Components Technical Reference Manual version 1.0

## 48.2.3 SWJ-DP Debug Port (SWD and JTAG)

The MCU core integrates an SWD/JTAG debug port (SWJ-DP). This port is an ARM-standard CoreSight debug port, featuring both a JTAG-DP (5-pin) interface and an SW-DP (2-pin) interface.

- The JTAG debug port (JTAG-DP) provides a 5-pin standard JTAG interface for connecting to the AHB-AP port.
- The Serial Wire Debug port (SW-DP) provides a 2-pin (Clock + Data) interface for connecting to the AHB-AP port.

In SWJ-DP, the 2 JTAG pins of SW-DP are multiplexed with some of the 5 JTAG pins of JTAG-DP.

In the figure below, JTDO reuses TRACESWO and TDO. This means that asynchronous tracing can only be implemented on SW-DP, not on JTAG-DP.

Figure 48-2 Debug Control System

### 48.2.3.1 JTAG-DP or SW-DP Switching Mechanism

The default debug interface is the JTAG-DP interface.

If the debug tool wants to switch to SW-DP, it must provide a dedicated JTAG sequence on JTMS (SWDIO) /JTCK (SWCLK) to disable JTAG-DP and enable SW-DP. This allows access to SW-DP using only the SWCLK and SWDIO pins.

The sequence is:

1. Output a JTMS (SWDIO)=1 signal for more than 50 JTCK periods
2. Output 16 JTMS (SWDIO) signals 0111\_1001\_1110\_0111 (MSB)
3. Output a JTMS (SWDIO)=1 signal for more than 50 JTCK periods

Figure 48-3 JTAG-DP to SW-DP Switching Timing

#### 48.2.4 Pin Arrangement and Debug Port Pins

Depending on the MCU package, there are different active pin counts. Therefore, some pin-related functions may vary from package to package.

##### SWJ Debug Port Pin

5 common I/O ports of MCU can be used as SWJ-DP interface pins.

Table 48-1 SWJ Debug Port Pin

| SWJ-DP Pin Name | JTAG Debug Port |                     | SW Debug Port |                                               |
|-----------------|-----------------|---------------------|---------------|-----------------------------------------------|
|                 | Types           | Description         | Type          | Debug Allocation                              |
| JTMS/SWDIO      | I               | JTAG Mode Selection | I/O           | Serial data input/output                      |
| JTCK/SWCLK      | I               | JTAG Clock          | I             | Serial clock                                  |
| JTDI            | I               | JTAG Data Input     | -             | -                                             |
| JTDO/TRACESWO   | O               | JTAG Data Output    | -             | TRACESWO (if asynchronous tracing is enabled) |
| NJTRST          | I               | JTAG Reset          | -             | -                                             |

##### Flexible SWJ-DP Pin Assignment

After reset (Power On or Pin Reset), all five pins used for SWJ-DP are designated as dedicated pins, immediately available for use by debug tools (Note: to use trace output, configure the register MCUTRA-CECTL). However, the MCU can disable some or all SWJ-DP ports, thereby releasing the relevant pins for use as GPIOs. For more details on how to disable SWJ-DP port pins, refer to the "Special Control Register (PSPCR) " in the "General-Purpose I/O (GPIO) " chapter.

Table 48-2 Flexible SWJ-DP Pin Assignment

| Available Debug Ports                  | Assigned SWJ IO Pins |                |            |            |            |
|----------------------------------------|----------------------|----------------|------------|------------|------------|
|                                        | JTMS/<br>SWDIO       | JTCK/<br>SWCLK | JTDI       | JTDO       | NJTRST     |
| All SWJ (JTAG-DP + SW-DP) -reset state | ✓                    | ✓              | ✓          | ✓          | ✓          |
| Disable JTAG-DP and enable SW-DP       | ✓                    | ✓              | Releasable | Releasable | Releasable |
| Disable JTAG-DP and disable SW-DP      | Releasable           | Releasable     | Releasable | Releasable | Releasable |

### Internal Pull-ups on JTAG Pins

According to the JTAG IEEE standard, it must be ensured that the JTAG input pins are not floating because these pins are directly connected to the MCU internals for controlling the debug functions. Special attention must also be paid to the JTCK/SWCLK pin, which is directly used for debug control clock functions. To avoid floating IO levels, the MCU has built-in internal pull-up resistors on the JTAG pins:

- NJTRST: Internal pull-up
- JTDI: Internal pull-up
- JTMS/SWDIO: Internal pull-up
- JTCK/SWCLK: Internal pull-up
- JTDO: Internal pull-up

In the absence of a connected debugger, user software can release JTAG IO for use as general-purpose I/O ports by setting the GPIO special control register. Since the internal pull-up is a weak pull-up of <100kΩ, it is recommended to use an external pull-up of 10kΩ.

### Using Serial Interfaces and Releasing Unused Debug Pins for GPIO

Some GPIOs can be released when using SWD, user software must change the GPIO configuration in the GPIO control register, so that the corresponding pins can be released as GPIO.

When debugging, the host does the following:

- Under system reset, allocate all SWJ pins (JTAG-DP + SW-DP).
- Under system reset, the debug host sends a JTAG sequence to switch from JTAG-DP to SW-DP.
- Still in the system reset state, the debug host sets a breakpoint at the reset address.
- The reset signal is released and the core stops at the reset address.
- From this debug port switch to SW-DP. Then, other JTAG pins are reallocated as GPIOs through user software.

#### Notice

For user software design, when debug pins need to be released, during the period from reset until user software releases the pins, these pins remain in input pull-up mode (NJTRST, JTMS, JTDI, JTCK, and JTDO).

### 48.2.5 SW Debug Port-SW Protocol Overview

The synchronous serial protocol uses two pins:

- SWCLK: Clock from master to slave
- SWDIO: Bidirectional

LSB is ahead when transferring data.

For SWCLK and SWDIO, it is recommended to use a 10kΩ pull-up on the circuit board.

## 48.2.6 TPIU (Trace Port Interface Unit)

### 48.2.6.1 Overview and Block Diagram

TPIU is a bridge between ITM and on-chip trace data.

Output data streams are packaged with trace source IDs and then captured by the Trace Port Analyzer (TPA).

Figure 48-4 TPIU Block Diagram

### 48.2.6.2 TRACE Pin Allocation

- Asynchronous Mode

Asynchronous mode requires 1 extra pin and is available in all packages. Asynchronous mode is only available when using serial line mode (not available in JTAG mode).

| TPIU pin name | Track Asynchronous Mode |                                |
|---------------|-------------------------|--------------------------------|
|               | Type                    | Description                    |
| TRACESWO      | O                       | TRACE asynchronous data output |

- Synchronous Mode

Synchronous mode requires 2 to 5 extra pins, depending on the length of the data being traced, and is only available on larger packages. In addition, synchronous mode is available in both JTAG mode and serial mode, and can provide higher bandwidth output capability than asynchronous trace.

| TPIU Pin Name | Track Sync Mode |                                                       |
|---------------|-----------------|-------------------------------------------------------|
|               | Type            | Description                                           |
| TRACECK       | O               | TRACE Clock                                           |
| TRACED[3:0]   | O               | TRACE synchronous data output can be 1, 2, or 4 bits. |

### TPIU TRACE Pin Allocation Rules

By default, these pins are not allocated. These pins can be configured by setting the TRACE\_IOEN and TRACE\_MODE bits in the MCU Debug Component Configuration Register (MCUTRACECTL). This configuration must be done by the debug host or CPU.

Also, the number of pins to assign depends on the trace configuration (asynchronous trace or synchronous trace).

- Asynchronous mode: 1 extra pin required
- Synchronous mode: 5 extra pins required
  - ▶ TRACECK
  - ▶ TRACED[0] (if port data length is configured as 1, 2, or 4)
  - ▶ TRACED[1] (if port data length is configured as 2 or 4)
  - ▶ TRACED[2] (if port data length is configured as 4)
  - ▶ TRACED[3] (if port data length is configured as 4)

To allocate TRACE pins, the debug host must configure the TRACE\_IOEN and TRACE\_MODE[1:0] bits in the MCU debug configuration register (MCUTRACECTL). By default, TRACE pins are not allocated.

This register is mapped on the external PPB bus and is reset by power-on (not pin reset). This register can be written by the debugger in the pin reset state.

| TPIU Pin Usage             |            |            | Assigned TRACE IO Pins |         |           |           |           |           |
|----------------------------|------------|------------|------------------------|---------|-----------|-----------|-----------|-----------|
| Tracking Mode              | TRACE_IOEN | TRACE_MODE | JTDO/TRACE-SWO         | TRACECK | TRACED[0] | TRACED[1] | TRACED[2] | TRACED[3] |
| No tracing (default state) | 0b0        | 0bXX       | Release <sup>(1)</sup> | Release | Release   | Release   | Release   | Release   |
| Asynchronous tracking      | 0b1        | 0b00       | TRACESWO               | Release | Release   | Release   | Release   | Release   |
| Sync tracking 1 bit        | 0b1        | 0b01       | Release <sup>(1)</sup> | TRACECK | TRACED[0] | Release   | Release   | Release   |
| Sync tracking 2 bits       | 0b1        | 0b10       | Release <sup>(1)</sup> | TRACECK | TRACED[0] | TRACED[1] | Release   | Release   |
| Sync tracking 4 bits       | 0b1        | 0b11       | Release <sup>(1)</sup> | TRACECK | TRACED[0] | TRACED[1] | TRACED[2] | TRACED[3] |

#### Note

1. Released when using serial wire mode. But when using JTAG, this pin is assigned to TDO.

### 48.2.6.3 MCU Internal TRACECLKIN Connection

In this MCU, the clock TRACECLKIN of TPIU is connected to the internal clock. The default clock of the MCU is the internal MRC oscillator. The frequency in reset state is different from the frequency after reset release. The reason is that since the default MRC calibration value is adopted in the system reset state, the MRC calibration value will be updated every time the system reset is released. Therefore, the Trace Port Analyzer (TPA) should not enable tracing (using the TRACE\_IOEN bit) during system reset, as the bit width of the synchronous frame packet under reset state differs from the packet after reset.

### 48.2.6.4 TPIU Register Usage Instructions

Reads and writes to TPIU APB registers are only possible when the TRCENA bit in the Debug Exception and Monitor Control Register (DEMCR) is set to 1. Otherwise, these registers will read as 0 (setting this bit enables the TPIU clock).

### 48.2.6.5 TPIU Configuration Instance

1. Setting TRCENA bit in the Debug Exception and Monitor Control Register (DEMCR) to 1.
2. Writing the desired value to the TPIU Current Port Size Register (CSPSR) (default value is 0x1 for 1-bit port size).
3. Writing 0x102 to the TPIU Formatter and Flush Status Register (default value).
4. Write TPIU select pin protocol to select synchronous mode or asynchronous mode. Example: 0x2 means asynchronous NRZ mode (similar to USART).
5. Writing 0x00 to the MCUTRACECTL.TRACE\_IOEN bit to allocate TRACE I/O for asynchronous mode.

6. Sending a TPIU synchronization packet (FF\_FF\_FF\_7F) at this point.
7. Configuring ITM and writing to the ITM Stimulus Port Register to output values.

## 48.3 Register Description

### 48.3.1 Register List

Base address: 0xE0042000

Table 48-6 Debug Controller (DBGC) Register Offset

| Offset | Register    | Description                              | Width | Access Host                  |
|--------|-------------|------------------------------------------|-------|------------------------------|
| 0x000C | CHIPID      | Chip Identification Register             | 32    | Debug IDE                    |
| 0x001C | MCUDBGSTAT  | DBG Status Register                      | 32    | CPU/Debug IDE <sup>(1)</sup> |
| 0x0020 | MCUSTPCTL   | Peripheral Debug Stop Control Register   | 32    | CPU/Debug IDE <sup>(1)</sup> |
| 0x0024 | MCUTRACECTL | Debug Component Trace Control Register   | 32    | CPU/Debug IDE <sup>(1)</sup> |
| 0x0028 | MCUSTPCTL2  | Peripheral Debug Stop Control Register 2 | 32    | CPU/Debug IDE <sup>(1)</sup> |

#### Note

1. Register bits are located in the PPB region and can only be accessed by the CPU in privileged mode.

### 48.3.2 Chip Identification Register (CHIPID)

Used to indicate company information and product model information.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|---|---|---|---|---|---|---|---|
| 0x000C | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Reset  | 0x584804A8   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Name   | CHIPID       |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |
| Access | RO           |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |   |   |

| Bit  | Name   | Function            | Description                                                                     | Access |
|------|--------|---------------------|---------------------------------------------------------------------------------|--------|
| 31:0 | CHIPID | Chip Identification | CHIPID[31:16]: ASCII code for XH, 0x5848<br>CHIPID[15:0]: product model, 0x04A8 | RO     |

### 48.3.3 DBG Status Register (MCUDBGSTAT)

DBG debugs power-on status check register.

| Offset | Bit Position |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |              |              |
|--------|--------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|---|---|---|---|---|---|---|---|--------------|--------------|
| 0x001C | 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1            | 0            |
| Reset  | 0x00000000   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   |              |              |
| Name   | Reserved     |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   | CDBGPWRUPACK | CDBGPWRUPREQ |
| Access |              |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |   |   |   |   |   |   |   |   | RW           | RW           |

| Bit  | Name         | Function                   | Description                                                                                               | Access |

| Half Word   | -                             | Half word, 16-bit data                                                                                                                                                                                                   |
| Word        | -                             | Words, 32-bit data                                                                                                                                                                                                       |
| Double Word | -                             | Double word, 64 -bit data.                                                                                                                                                                                               |
| IAP         | -                             | It refers to reprogram the MCU's Flash during the running of a user program (programming in the application).                                                                                                            |
| ICP         | -                             | It means that the MCU's Flash of the MCU can be programmed by using JTAG protocol, SWD protocol or bootstrap program when the device is installed on the user application circuit board (in-circuit/online programming). |
| AHB         | Advanced High-performance Bus | Advanced High-Performance Bus                                                                                                                                                                                            |
| APB         | Advanced Peripheral Bus       | Advanced peripheral bus                                                                                                                                                                                                  |
| DMA         | Direct Memory Access          | Direct memory access                                                                                                                                                                                                     |
| TIM/TMR     | -                             | Timer                                                                                                                                                                                                                    |
